Biographical Sketch

Nicolás Palopoli has been computational biologist since 2005. He studied Biotechnology at *Universidad Nacional de Quilmes* (UNQ) in Buenos Aires, Argentina, where he also got his PhD title in Basic and Applied Sciences. He was a postdoctoral research fellow at *Universidad de Buenos Aires*, Argentina and University of Southampton, UK. He recently returned to the Structural Bioinformatics Group (UNQ) as Assistant Researcher from the National Scientific and Technical Research Council of Argentina (CONICET). He is always interested in understanding the structural properties, biological function and evolutionary relationships of proteins. His current research projects involve protein-protein interactions mediated by Short Linear Motifs (SLiMs) and the special features associated with protein intrinsic disorder. He is also a patient lecturer, respectful colleague and proud husband and dad.

Study of the Variability of the Native Protein Structure

Introduction

Proteins are flexible molecules. After being translated from a messenger RNA by a ribosome, a protein folds into its native structure (the structure of lowest free energy), which is suitable for carrying out its biological function. Although the native structure of a protein is stabilized by physical interactions of atoms including hydrogen bonds, disulfide bonds between cysteine residues, van der Waals interactions, electrostatic interactions, and solvation (interactions with solvent), the structure still admits flexible motions. Motions include those of side-chains, and some parts of main-chains, especially regions that do not form the secondary structures, which are often called loop regions. In many cases, the flexibility of proteins plays an important or essential role in the biological functions of the proteins. For example, for some enzymes, such as triosephosphate isomerase (Derreumaux and Schlick, 1998), loop regions that exist in vicinity of active (i.e., enzymatic reaction) sites, takes part in binding and holding a ligand molecule. Transporters, such as maltose transporter (Chen, 2013), are known to make large open-close motions to transfer ligand molecules across the cellular membrane. For many motor proteins, such as myosin V that “walk” along actin filament as observed in muscle contraction (Kodera and Ando, 2014), flexibility is the central for their functions.

Reflecting such intrinsic flexibility of protein structures, differences are observed in protein tertiary structures determined by experimental methods such as X-ray crystallography, nuclear magnetic resonance (NMR) when they are solved under different conditions. In this article, we start by introducing two studies that surveyed such structural differences of the same proteins found in the public repository of protein structures, Protein Data Bank (PDB) (Berman *et al.*, 2000), which contains over 136,000 entries at the time of writing this article (December 2017). Thus, structural variability of a protein can be observed by comparing static structures determined under different conditions. Experimentally, conformational variability can be measured by NMR and other spectroscopic techniques (Greenleaf *et al.*, 2007; Parak, 2003; Hinterdorfer and Dufrene, 2006). Alternatively, structural changes, i.e., flexibility, can be observed for a single protein structure by performing computational simulations or predictions of dynamics of the protein structure. Computational methods for elucidating protein structure flexibility are also useful for estimating the free energy of molecular interactions as well as structure refinement needed when determining protein tertiary structures. In this article we overview such computational tools with some examples of application.

Discussion in this article is focused on protein structures that have overall stable fixed structures (with some flexibility in side-chains and parts of the main-chain, e.g., loops). However, note that there is a different class of proteins that do not form stable structures at all under physiological conditions. Such proteins are called intrinsically disordered proteins (IDPs) (Dunker *et al.*, 2008). IDPs were not paid much attention for a long time since their structures cannot be determined by regular experimental structural biology methods, such as X-ray crystallography or NMR, due to their intrinsic flexibility. But from around 2000, IDPs attracted large attention as long-neglected protein structures, and have been studied extensively since then. IDPs have characteristic amino acid sequence patterns, from which IDPs can be predicted from their amino acid sequences (Ferron *et al.*, 2006). It is estimated that about 5%–30% of amino acid sequences in an organism's proteome are intrinsically disordered (Oates *et al.*, 2013). It was found that disordered regions are often responsible for establishing protein-protein interactions, especially for proteins that interact with multiple proteins. The D2P2 database (Oates *et al.*, 2013) provides predicted IDPs in over 1700 genomes by many existing IDP prediction methods.

Fundamentals

Conformational Transitions Observed in Experimentally Determined Structures

Structural variability of proteins can be observed by comparing structures that are experimentally determined in different conditions. Kosloff and Kolodny (2008) performed a systematic study on protein structure variability relative to the sequence identity including cases that two structures are 100% identical in their sequences. The dataset was comprised of 19,295 protein chains taken from the April 2005 PDB, which are longer than 35 residues and were determined at a resolution of 2.5 Å or higher using X-ray crystallography. To eliminate redundant protein chains in the dataset, no pairs have 100% sequence identity and less than 1 Å root-mean square deviation (RMSD) between each other. Out of the 1941 chain pairs with 100% sequence identity in this dataset, there were 444 (22.9%) pairs with an RMSD of 3 Å or larger and 158 (8.1%) pairs with an RMSD over 6 Å. Such cases included chain pairs that have very different structures of over a 10 Å RMSD. They classified the sources of structural dissimilarity, which included different quaternary protein-protein interactions, protein-ligand and protein-DNA/RNA interactions, different crystallization conditions such as pH or salt conditions, and alternative crystallographic conformations of the same proteins. Thus, as is also discussed in other studies (Goh *et al.*, 2004; Boehr *et al.*, 2009), one of the main reasons for the existence of alternative conformations is due to physical interactions with other molecules. Most large conformational changes observed in protein structures are inherent to their biological functions, as Gan *et al.* (2002) pointed out in their work.

Fig. 1 Superimpositions of protein structures with a large conformational change. (A) Structure of DNA polymerase β in open (PDB ID: 9ICX, chain A, colored in light grey) and closed (PDB: 1BPY, chain A, colored in black) conformations. DNA in the crystal structures are omitted in the figure. (B) Structure of diphtheria toxin in open (PDB: 1DDT, chain A, colored in light grey) and closed (PDB: 1MDT, chain A, colored in black) conformations.

We show several examples of large conformational change of proteins. The first example is human DNA polymerase β in open and closed conformations (**Fig. 1(A)**) (Pelletier *et al.*, 1996; Sawaya *et al.*, 1997). The RMSD between the two structures is 5.3 Å. This conformational change is needed for its biological function, catalytic polymerization of nucleotides as well as binding and releasing DNA. The second example is diphtheria toxin in open and closed conformations (**Fig. 1(B)**). The RMSD is 11.0 Å (Bennett and Eisenberg, 1994). This protein has three domains, the catalytic domain, the transmembrane domain, and the C-terminus receptor binding domain. In the two structures superimposed in **Fig. 1(B)**, the arrangement of these three domains is very different. Particularly, the receptor domain shown on the right side of the figure is distant from the rest of the structure in the open conformation. This drastic conformational change is speculated to be essential for penetrating the host cell membrane, a critical step for intoxication.

Fig. 2 shows three more examples where binding with other molecule is involved in the conformational change. **Fig. 2(A)** shows structure of export chaperone FliS in *Aquifex aeolicus* (Evdokimov *et al.*, 2003). FliS acts as a flagellar export chaperone, which binds specifically to FliC to regulate its export and assembly process. The structure of unbound FliS is an antiparallel four-helix bundle (**Fig. 2(A)**, Left). The N-terminal cap blocks the hydrophobic binding site in FliS when FliC is absent. Upon complex formation with FliC, there is a substantial conformation change in FliS (**Fig. 2(A)**, Right), where the N-terminus in FliS displaces to form a short helix on one side of the bundle (on the right side of the panel), interacting with one helical segment in FliC. The RMSD between the two conformation is 6.4 Å. The next one is a textbook example, calmodulin (**Fig. 2(B)**). Calmodulin undergoes a large conformational change between the apo (i.e., non-ligand binding) state and the calcium-binding state (Yamniuk and Vogel, 2004). In calcium-free calmodulin, each globular domain is made up of four helices running in parallel/antiparallel orientations to each other (**Fig. 2(B)**, Left). In the calcium-bound form, the interdomain region forms a long α -helix (the right panel) instead of two short α -helices in the apo form. This helical rearrangement exposes hydrophobic binding patches on the surface of each domain, which binds to peptide sequences in target enzymes. The RMSD between the two structures is 12.9 Å. The last example in **Fig. 2** is RfaH, a member of a universally conserved family of transcription factors (**Fig. 2(C)**). In its closed form, RfaH C-terminal domain (CTD) forms an α hairpin that masks an RNA Polymerase binding site in RfaH N-terminal domain (NTD) (Belogurov *et al.*, 2007) (**Fig. 2(C)**, Left, the light grey region). But upon release from RfaH-NTD, RfaH-CTD refolds into a β barrel that binds to the ribosome to activate translation (the right panel) (Burmam *et al.*, 2012). The RMSD between the two structures of the RfaH-CTD is 14.0 Å. The dramatic switch from α helix to β barrel transforms the function of RfaH from transcription factor to translation factor.

Molecular Dynamics

From this subsection, we introduce several computational methods that can simulate or model structural variability of proteins.

Molecular dynamics (MD) simulation is a computer simulation technique to investigate the movement of atoms and molecules based on the principles of physics. Since its first application for biomolecules published 40 years ago (Mccammon *et al.*, 1977), it has become a popular and standard tool for studying biomolecular motion. The basic concepts of MD are (1) to divide time into discrete time steps (1 or 2 fs, generally) and (2) to solve Newton's equations of motion (Eq. (1)) at every time step:

$$F(\mathbf{x}) = -\nabla U(\mathbf{x}) = m \frac{d^2 \mathbf{x}}{dt^2} \quad (1)$$

Fig. 2 Conformational transitions upon protein-ligand interactions. (A) Structure of FliS in unbound state (PDB: 1ORJ, chain A, left panel) and bound state (PDB: 1ORY, right panel). FliC is colored in light grey in the FliS-FliC complex. (B) Structure of calmodulin in the unbound state (PDB: 1DMO, chain A) and the calcium-binding state (PDB: 1CLL, chain A). Calcium ions in the crystal structure are shown as spheres colored in light grey on the right panel. (C) Structure of full-length RfaH in closed form (PDB: 2OUG, chain A) and RfaH C terminal domain in open form (PDB: 2LCL, chain A). RfaH N terminal domain is colored in light grey in the closed state (left).

$F(\mathbf{x})$, $U(\mathbf{x})$, $\mathbf{x}$, and m are a force, a potential energy, a coordinate of an atom, and a mass of an atom, respectively. Since the system is composed of a number of atoms, Eq. (1) cannot be solved analytically. Therefore, the trajectory of an atom can be obtained by integrating the potential energy at every time step numerically. The most famous algorithm for the numerical integration is Verlet algorithm (Verlet, 1967). A potential energy acting on an atom, $U(\mathbf{x})$, is calculated by a force field, which is composed of a functional form representing each force terms. Basically, the force field is composed of bonded and nonbonded terms (Eq. (2)).

$$U_{total} = U_{Bonded} + U_{Nonbonded} \quad (2)$$

A bonded term is a pairwise interaction energy of atoms that are connected by covalent bonds. It is composed of four terms; bond, angle, torsion, and improper torsion (Fig. 3, Eq. (3)). Different from the previous three terms that work on all atoms, improper torsion term only acts on special sets of atoms such as a peptide bond and benzene and prevents a deviation from planarity of the atom sets.

Fig. 3 Definitions of angles in the force field. (A) The bond length l , bond angle θ and the torsion angle, (φ) . (B) Improper torsion.

$$\begin{aligned}
 U_{\text{Bonded}} &= U_{\text{Bond}} + U_{\text{angle}} + U_{\text{Torsion}} + U_{\text{Improper}} \\
 &= \sum_{\text{Bonds}} \frac{k_{bi}}{2} (l - l_{i,eq})^2 + \sum_{\text{Angles}} \frac{k_{\theta i}}{2} (\theta_i - \theta_{i,eq})^2 + \sum_{\text{Torsions}} \sum_n \frac{V_{n,i}}{2} \left[1 + \cos(n(\varphi)_i - (\varphi)_{i,0}) \right] + \sum_{\text{Improper}} \frac{k_{(\varphi)i}}{2} ((\varphi)_i - (\varphi)_{i,eq})^2 \quad (3)
 \end{aligned}$$

The bond and the angle terms reflect vibration of bond lengths and angles along with covalent bonds. l and θ are the bond length and bond angle at the current state (Fig. 3(A)). The parameters, k_b , l_{eq} , k_θ , and θ_{eq} , are force constants and values of a bond in the equilibrium state. They are derived from gas phase spectroscopy and/or crystal structures of small molecules. The functional forms of the terms are approximated as harmonic oscillators. The torsion term calculates bond energies associated with proper torsion angles, (φ) in Fig. 3(A). Since it is periodic, it has a cosine functional form, and the parameters, V_n and $(\varphi)_0$ are obtained from quantum mechanics calculation. The improper torsion has a functional form of a harmonic oscillator (Fig. 3(B)).

A nonbonded term describes the long-range interaction of atoms, which consists of van der Waals and Coulomb potentials:

$$U_{\text{Nonbonded}} = U_{\text{van der Waals}} + U_{\text{Coulomb}} = \sum_{i=1}^N \sum_{j=i+1}^N \left\{ 4\epsilon_{ij} \left[\left(\frac{\sigma_{ij}}{r_{ij}} \right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}} \right)^6 \right] + \frac{q_i q_j}{4\pi\epsilon r_{ij}} \right\} \quad (4)$$

In the van der Waals term, σ_{ij} and r_{ij} are the radius and well depth, respectively. They are calculated by taking the arithmetic mean ($\sigma_{ij} = (\sigma_{ii} + \sigma_{jj})/2$) and the geometric mean ($\epsilon_{ij} = \sqrt{\epsilon_{ii} \epsilon_{jj}}$) of parameters of the di-atomic system. For the Coulomb term, q_i is an atomic charge of atom i , and ϵ is a dielectric constant that reflects a solvent polarity (e.g., $\epsilon = 1$ for vacuum, $\epsilon = 4$ for protein, and $\epsilon = 80$ for water in implicit solvent model).

Most biological reactions take place in a cell, surrounded by water molecules; thus it is important to consider the effects of water. In MD and other simulation methods, water molecules can be treated in two ways; an implicit solvation and an explicit solvation model. An implicit solvation model (Fig. 4(A)), which is also called continuum solvent, considers solvent as a continuous isotropic medium. It approximates solvent molecules as a homogeneously polarizable, averaged medium (Skyner *et al.*, 2015). The main parameter for the continuum model is a dielectric constant ϵ , and supplementary parameters are used to describe solvent properties such as surface tension. Atoms in solution are represented as spherical cavities with atomic charges embedded in homogeneously polarizable solvent (Fig. 4(A)). An explicit solvation model (Fig. 4(B)) treats water molecules explicitly. This is a more realistic model than the implicit solvation model, since physical interaction between a solute and solvent molecules can be directly calculated from the same functional form of the force field. However, the number of atoms in the system is increased drastically in an explicit solvation model; therefore, it takes much more time to calculate potential energy of the solute atoms and trajectory of them. The most famous model of explicit water is TIP3P (Jorgensen *et al.*, 1983).

Coarse-Grained Protein Structure Models

If the size of a protein to simulate is very large, a MD simulation for a biologically relevant time span with an atomistic representation may be computationally infeasible. One way to solve this issue is to represent a protein structure with a simplified (coarse-grained, CG) model. In a coarse-grained model, the complexity of the system is reduced by grouping atoms together into pseudo particles (Barnoud and Monticelli, 2015). Reducing the number of particles decreases the number of interactions to calculate and makes the energy landscape smoother, both of which contribute to shortening the computational time for simulation compared to an atomistic model. The functional form of a CG force field is similar to that for an atomistic force field. The parameters of a CG force field are determined to be able to produce similar trajectories as atomistic MD simulation.

One of the well-known CG force fields is MARTINI (Marrink *et al.*, 2007). Generally, the MARTINI force field maps a group of four heavy atoms to one interaction site (bead). The beads of amino acids are mainly classified into four; polar, nonpolar, apolar, and charged. These are further categorized into subclasses based on hydrogen-bonding capabilities and polarity, resulting in 18 types of beads. Comparing to an atomistic simulation, the MARTINI force field yields a speed-up of 2–3 orders of magnitude. Other CG protein models include UNRES (United RESidues) (Liwo *et al.*, 2004, 2005) and CABS (C-Alpha, c-Beta, Side-chain)

Fig. 4 Two solvent models. (A) The implicit solvent model, where solvent is represented as a dielectric constant of ϵ . (B) The explicit solvent model. A water molecule is represented as a bent line with oxygen and hydrogen atoms colored in red and white, respectively. Interactions between atoms in water molecules and proteins are computed in the same way using the equations of the force field used.

(Kolinski, 2004). In the UNRES model, each amino acid residue is represented by only two interaction sites, an ellipsoid at the side-chain centroid and another one at the center of $C\alpha-C\alpha$ bond. The force field of UNRES is derived as a restricted free energy function, which considers averaging the all-atom energy over the degrees of freedom that are neglected in the UNRES model. Thus, UNRES is a physics-based united residue force field. In the CABS model, each amino acid residue is represented by four interaction centers; the $C\alpha$ atom, the center of $C\alpha-C\alpha$ bond, the $C\beta$ atom, and the center of mass of the side-group. To facilitate faster simulations, $C\alpha$ atoms in the CABS model are projected onto a cubic lattice with 0.61 Å spacing. The force field of CABS is based on statistical potentials that mimic averaged interactions observed in globular protein structures in PDB.

Elastic Network Models

As discussed in Section “Coarse-Grained Protein Structure Models”, coarse-grained models of protein dynamics are used to reduce the computational cost of analysis. Some of the simplest such models are elastic network models (ENMs). In an ENM, pairwise interactions in a structure are modelled as Hookean springs at equilibrium, i.e., a model where beads representing interaction centers (e.g., amino acid residues) are connected by springs. In other words, the potential energy function has the form $\sum \frac{1}{2}\gamma_{ij}(r_{ij} - r_{ij}^0)^2$, where γ_{ij} are positive constants characterizing the stiffness of the interaction and r_{ij}^0 is the initial distance between atoms i and j ; in contrast to the general form of MD potentials given in Section “Coarse-Grained Protein Structure Models”, ENMs effectively model all interactions as bonds. Tirion considered an all-atom elastic network model with all γ_{ij} identical and atom pairs interacting if their distance was less than the sum of their van der Waals radii and an arbitrary cutoff (Tirion, 1996). That study established that normal mode analysis (NMA), which decomposes the general motion of a system into linearly independent modes of harmonic motion, of such potentials could reproduce the density of slow normal modes of more complicated and costly potentials. Hinsen showed that the slow modes of ENMs can in fact reproduce large-scale deformation, even when only α carbons were considered (Hinsen, 1998). Such coarse ENMs with a single point mass per residue have become popular; in the following sections, we discuss two such models.

Anisotropic network model

Although not chronologically the first residue-level ENM, the anisotropic network model (ANM) is the more general of the two we discuss here. Introduced by Doruker *et al.* (2000) and expounded by Atilgan *et al.* (2001) and Eyal *et al.* (2006), the ANM potential has all γ_{ij} identical and all interaction cutoffs identical (e.g., 7 Å). Here, the NMA is performed with respect to the Cartesian coordinates of each α carbon; i.e., the Hessian of the potential has the block matrix form

$$H = \begin{bmatrix} H_{ii} & \cdots & H_{ij} \\ \vdots & \ddots & \vdots \\ H_{ji} & \cdots & H_{jj} \end{bmatrix} \quad (5)$$

where each block expands to

$$H_{ij} = \begin{bmatrix} \frac{\partial^2 U_{ij}}{\partial x_i \partial x_j} & \frac{\partial^2 U_{ij}}{\partial x_i \partial y_j} & \frac{\partial^2 U_{ij}}{\partial x_i \partial z_j} \\ \frac{\partial^2 U_{ij}}{\partial y_i \partial x_j} & \frac{\partial^2 U_{ij}}{\partial y_i \partial y_j} & \frac{\partial^2 U_{ij}}{\partial y_i \partial z_j} \\ \frac{\partial^2 U_{ij}}{\partial z_i \partial x_j} & \frac{\partial^2 U_{ij}}{\partial z_i \partial y_j} & \frac{\partial^2 U_{ij}}{\partial z_i \partial z_j} \end{bmatrix} \quad (6)$$

Computing the eigenpairs of H yields $3N - 6$ eigenpairs corresponding to internal modes. The eigenvalues λ_k and frequencies ω_k of the modes are related by

$$\omega_k^2 = \gamma \lambda_k \quad (7)$$

Although H is not invertible, we can construct a pseudo-inverse

$$H^{-1} = \sum_{k=7}^{3N} \frac{u_k u_k^T}{\lambda_k} \quad (8)$$

where u_k are eigenvectors and eigenpairs are in increasing order by eigenvalue magnitude. Cross-correlations between the equilibrium fluctuations of residues i and j are then given by

$$C_{ij} = \frac{\text{tr}(H_{ij}^{-1})}{\sqrt{\text{tr}(H_{ii}^{-1}) \text{tr}(H_{jj}^{-1})}} \quad (9)$$

where H_{ij}^{-1} is the (i,j) th 3×3 block of H^{-1} . The B-factor of atom i , defined as $8\pi^2$ times the mean squared displacement of atom i ,

$$B_i = \frac{8\pi^2 k_B T}{3\gamma} \text{tr}(H_{ii}^{-1}) \quad (10)$$

where k_B is the Boltzmann constant and T is the temperature.

ANM has been used to study the dynamics of biomolecules that are related to their biological functions (Navizet *et al.*, 2004; Keskin *et al.*, 2002).

Gaussian network model

Compared to ANM, which can evaluate directional preferences of vibrational dynamics of proteins, Gaussian Network Model (GNM) only provides displacements and correlations between displacements of amino acid residues (Bahar *et al.*, 1997). Mathematically, any information obtained from GNM can also be obtained from ANM; however, if only isotropic information is needed, GNM is computationally cheaper. To calculate the isotropic cross-correlations and B-factors under a GNM, we start from the graph Laplacian Γ of the graph where vertices correspond to atoms and edges correspond to interactions. Then, the cross-correlations are given by

$$C_{ij} = \frac{\Gamma_{ij}^{-1}}{\sqrt{\Gamma_{ii}^{-1} \Gamma_{jj}^{-1}}} \quad (10)$$

where Γ^{-1} is a pseudoinverse as in Section “Anisotropic network model”, and the B-factors are given by

$$B_i = \frac{8\pi^2 k_B T}{3\gamma} \Gamma_{ii}^{-1} \quad (11)$$

Residue fluctuations computed from GNM have been shown to agree with the X-ray crystallographic B-factor, which reflects fluctuation of each atom at its position in the crystal structure (Bahar *et al.*, 1998). GNM has also been used for characterizing functional motions of proteins (Yang and Bahar, 2005) and macromolecules, such as ribosome (Wang *et al.*, 2004).

Flexpred

Variability of positions of residues in a protein structure can be also predicted from structural features of amino acids. Jamroz *et al.* (2012) developed FlexPred, which uses support vector regression (SVR) to predict residue fluctuations observed in 10 ns MD simulations, with a mean error in tests of 1.1 Å. Fluctuation is defined as

$$\sqrt{\langle (\Delta R_i)^2 \rangle^{\text{ref}}} = \sqrt{\frac{1}{T} \sum_{t_j=1}^T (x_i(t_j) - x_i^{\text{ref}})^2} \quad (12)$$

where T is the number of frames in the MD trajectory, $x_i(t_j)$ is the position of the α carbon of residue i at time t_j , and x_i^{ref} is the position of the α carbon of residue i in the protein structure. Structural features for each α carbon/residue that were found to be useful as input to SVR include distance to the structure's center of mass, the number of surrounding residues that are in contact, the

number of hydrophobic/hydrophilic contacts, solvent-accessible surface area, residue depth (the distance of the residue from protein surface), and secondary structure type.

Application and Case Studies

In this section we provide available software for analysing protein structure variability with some example applications.

Examples of Structural Variability in Protein Families

Structural variation of a protein can be quantified by superimposing the structures. Structure superimposition can help us reveal conserved regions among the structures which may be of functional importance as well as structure divergence and flexibility.

There have been a variety of multiple structure alignment methods developed over the years, which employ different scoring functions and different heuristics. Two examples are MAMMOTH-mult (Lupyan *et al.*, 2005) (see “Relevant Websites section”) and POSA (Ye and Godzik, 2005) (see “Relevant Websites section”). Both methods first conduct all pairwise structure alignments and constructs a dendrogram from pairwise similarity scores. Then, following the dendrogram, pairwise structure alignment is performed from leaf nodes, and finally all the structures are superimposed. This superimposition then undergoes an iterative refinement process (progressive alignment).

Multiple structure alignment is useful for understanding structural variability of single protein as well as structures of a protein family. Fig. 5 shows such an example, an alignment of three lectins, which have the legume lectin-like fold. Lectins are a group of carbohydrate binding proteins with large variation in size and structure. Characteristics of the lectin fold is the presence of a two

Fig. 5 Structure variation of proteins containing lectin fold. (A) Ribbon diagrams of three structures containing legume lectin-like fold. From left to right: Peanut lectin (PDB: 2PEL, chain A), Spermadhesin (PDB: 1SPP, chain A), Glucanase (PDB: 2AYH, chain A). All structures all shown in the same orientation. Common core identified in the POSA alignment are colored in red. Residues in common core are: residues 44–48, 51–53, 64–69, 200–209, 217–228 in 2pel-A; residues 28–35, 44–49, 85, 87–95, 97–108 in 1spp-A; residues 62–66, 69–77, 175–184, 203–214 in 2ayh-A. Beta sheets are colored in black. Helices and loops are colored in grey. (B) Superimposition of all structures. Structure alignments were produced using POSA.

Table 1 Popular molecular dynamics software

Name	Website
Amber	ambermd.org
CHARMM	www.charmm.org

Desmond	www.deshawresearch.com/resources_desmond.html

β -sheets positioned almost in parallel (Chandra *et al.*, 2001). Although all structures with lectin fold possess the β -sheets with the particular geometry, curvature of a sheet and the presence of binding site loops and hydrophobic cores vary among those structures (Fig. 5(A)). The multiple structure alignment by POSA overlays β -sheets of the three proteins and particularly reveals that all three proteins possess a common core of 36 amino acids, three β strands shown in red in Fig. 5(B). The average RMSD between three structure pairs is 3.0 Å. Compared with peanut lectin (Left in Fig. 5(A)), spermadhesin (Middle) and glucanase (Right) have an RMSD of 2.88 Å (for aligned 80 residues) and an RMSD of 3.02 Å (for aligned 172 residues), respectively.

Software for Molecular Dynamics Simulations

MD can be performed using several program packages to simulate protein flexibility. Table 1 lists popular MD simulation programs. All of the programs are free for academic users. The first MD package, Amber (Assisted Model Building with Energy Refinement) (Case *et al.*, 2005), was originally developed for refining NMR structures. The name 'Amber' refers to both force fields for the simulation of biomolecules and the MD program package. The most widely used force field versions are Amber94, Amber99SB, and Amber03. The next one, CHARMM (Chemistry at HARvard Macromolecular Mechanics) (Brooks *et al.*, 2009), also refers to both force fields and the program package. It was originally developed by Martin Karplus of Harvard University, USA. It is the oldest biomolecular MD package listed in Table 1. CHARMM-GUI (see "Relevant Website section") provides a web-based graphical tools for setting up input files for the simulation. GROMACS (GRONingen MACHine for Chemical Simulations) (Pronk *et al.*, 2013) typically runs 3–10 times faster than other MD programs. Unlike Amber and CHARMM, GROMACS does not have its own force field. Instead, it can import Amber, CHARMM, GROMOS, and the OPLS force field to run MD simulation. The unique feature of the program is that it is an open-source software released under the GPL license. NAMD (NANoscale Molecular Dynamics) is developed by the Theoretical and Computational Biophysics Group at the University of Illinois, Urbana-Champaign, USA (Phillips *et al.*, 2005). It is designed to efficiently run on parallel machines for simulating large molecules. The program has high compatibility with other MD programs such as CHARMM, since NAMD has same input, output, and force field formats as CHARMM.

Desmond is developed by D.E. Shaw Research (Bowers *et al.*, 2006). The program uses its novel parallel algorithms and numerical methods to achieve high computing performance. Desmond can import AMBER, CHARMM, and the OPLS force field to run MD simulation.

MD-Based Protein Structure Model Refinement

From Sections "MD-Based Protein Structure Model Refinement", "Refinement of Structures from Electron Microscopy Data", "Protein Folding" and "Free Energy Calculation" we will discuss notable applications of MD simulation for addressing protein structure variability. The first one is structure refinement for computationally modelled protein structure models. Protein structures can be computationally modelled with a reasonable accuracy if a structure of a related protein is already solved and available in PDB. The protein structure modelling technique that uses known structures as a template is called homology modelling or comparative modelling (Fiser, 2010). However, structure models usually still have deviation from the correct (native) structure of the protein, which may be as subtle as side-chain orientations to as large as a domain or loop motion relative to the native structure. The basic assumption of using MD for refining a structure model is that the conformational ensemble generated by MD simulation from the model contains a better structure that is closer to the native structure. The approach can also be applied to structure models built from low-resolution experimental data such as low-resolution X-ray crystallography (McGreevy *et al.*, 2014) and cryo-electron microscopy (cryo-EM) density maps (Singharoy *et al.*, 2016).

In the field of protein structure prediction, It has been recognized that running MD simulations for a structure model does not improve a model consistently, but rather drifts the structure away from the native structure because the conformational space is very large. However, the situation has changed in 2012, when MD-based methods were developed that refined models consistently in a protein structure prediction contest, the Critical Assessment of Techniques for Protein Structure Prediction (CASP) (Nugent *et al.*, 2014). Since then several MD-based structure refinement methods have been developed. These methods typically run MD with constraints so that the overall structure does not change drastically. Also the methods combine a structural averaging step and cross-check structures with additional structure evaluation scores (Mirjalili and Feig, 2013; Lee *et al.*, 2018; Terashi and Kihara, 2018). A drawback of the current methods is that the structure improvement they can achieve is small due to the constraints applied in the simulation, which do not allow large conformational changes in the model.

Refinement of Structures From Electron Microscopy Data

MD is also used for refining protein structures derived from low-resolution experimental data. The experimental data referred to here is the three-dimensional reconstruction of electron microscopy (EM) data, commonly referred to as EM maps. The fundamental methodology for combining MD approaches and experimental data is to perform the MD with an additional metric meant to measure the quality of fit between the atomic model and the EM map.

One method for measuring quality of fit is to convert the EM map data into a potential energy landscape. In this methodology, high density regions of the EM map will have low energy penalties for atoms to occupy that space, while low density regions will have higher energy penalties for atoms to occupy that space. The energy term is then added to the rest of the terms in an MD simulation (Eq. (3)). The most popular method which applies a quality-of-fit metric in this way is Molecular Dynamics Flexible Fitting (MDFF) (Singharoy *et al.*, 2016). An alternative metric for fit quality is cross correlation. The cross correlation between an atomic model and an EM map is determined by generating a simulated density map from the atomic model and determining the similarity of the simulated and experimental maps. A popular method which implements this kind of quality of fit metric is ROSETTA (Dimaio *et al.*, 2015). It is important when implementing these kinds of refinement techniques to remember that the refinement can only be as good as the experimental data allows. As the resolution of EM maps decreases, the extent to which multiple refinement techniques agree with each other will tend to decrease (Monroe *et al.*, 2017).

Protein Folding

Many proteins fold over a time scale on the order of millisecond or longer. Some proteins in the low millisecond range are Trp cage and Villin headpiece with sizes of 20 and 35 residues, respectively. These two α -helical proteins have successfully been simulated from unfolded states to folded states in simulations lasting 10 ns to 1 ms (Simmerling *et al.*, 2002; Duan and Kollman, 1998), and achieving C α RMSDs of 0.97 and 3.0 Å, respectively. On an even larger scale, the folding and unfolding of ubiquitin, a 76 residue $\alpha\beta$ protein, has been studied through high temperature, 1 ms simulations to an RMSD of 0.5 Å to the crystal structure of the protein (Piana *et al.*, 2013).

Free Energy Calculation

One of the most interesting applications of MD simulation is free energy calculation of a system. From a statistical thermodynamics point of view, free energy calculation is based on the ergodicity hypothesis, which claims that all possible microstates in the phase space can be covered by a trajectory of a system in a long time. With this hypothesis, we can assume that the average of an observable, such as enthalpy, over time is the same as its statistical ensemble. One of the classical example of this application is a protein folding energy landscape (Lei *et al.*, 2007).

Another useful application of free energy calculation is protein-ligand binding free energy (ΔG_{bind}) using The Molecular Mechanics energies combined with the Poisson–Boltzmann and Surface Area continuum solvation (MM/PBSA) method (Genheden and Ryde, 2015). MM/PBSA starts by generating MD trajectories of a protein-ligand complex, a protein, and a ligand. From the trajectories, snapshots of the system are picked up with a certain time interval. The Gibbs free energy of a molecule at a snapshot is calculated as:

$$G = E_{\text{Bond}} + E_{\text{vdW}} + E_{\text{Coul}} + G_{\text{pol}} + G_{\text{np}} - TS \quad (13)$$

E_{Bond} , E_{vdW} , and E_{Coul} are bonded term, van der Waals, and Coulomb force of a molecule, respectively. The three terms are calculated by the molecular mechanics force field (MM). G_{pol} and G_{np} are solvation energies of polar and nonpolar atoms of a molecule, obtained by solving the Poisson-Boltzmann equation for polar atoms and is proportional to surface area for nonpolar atoms. Although the MD trajectory is obtained from explicit solvent condition, the solvation energy is calculated with implicit solvation (PBSA). The last term, TS in Eq. (13) is entropy, calculated from normal mode analysis, multiplied by absolute temperature.

By taking average of Gibbs free energy across snapshots, binding free energy is calculated as follows:

$$\Delta G_{\text{bind}} = \langle G_{\text{Protein-Ligand}} \rangle - \langle G_{\text{Protein}} \rangle - \langle G_{\text{Ligand}} \rangle \quad (14)$$

$\langle G_i \rangle$ is an average of Gibbs free energy of a molecule i . The MM/PBSA has been successfully applied to estimating binding free energies of drugs (Zoete *et al.*, 2003; Pearlman, 2005).

Protein Flexibility Prediction With Flexpred

As discussed in Section “FlexPred”, flexibility of a protein structure can be predicted from structural features of amino acids in the structure. The method, FlexPred is available as a web server (see “Relevant Websites section”) and downloadable software (Peterson *et al.*, 2017). Fig. 6 shows an example of prediction for bovine angiogenin (PDB: 1AGI, 125 residues long). The plot shows flexibility, how far in Euclidean distance (Å) each amino acid moves on average (in 10 ns MD simulation) along the protein chain (Eq. (12)). At the bottom of the page, there are links to download the fluctuation predictions in CSV form and in the B-factor field of a PDB file. In this example, the predicted fluctuations and crystallographic B-factors correlate with correlation coefficient 0.82. Fig. 6(B) shows a side-by-side comparison of the predicted fluctuations (Left) and the B-factors (Right).

Fig. 6 Example of protein structure flexibility prediction. FlexPred was used. (A) Predicted fluctuation of residues of bovine angiogenin (PDB ID: 1AGI). The y-axis shows the fluctuation (Eq. (12)) of each residue. (B) Predicted fluctuation mapped on residues in the PDB file. Values are stored in the B-factor field of the PDB file. Left, prediction; Right, structure colored by crystallographic B-factor of 1AGI.

Conclusion

Proteins are flexible molecules. Some motions are important for biological function of proteins. How the structure of a protein varies can be obtained if the protein structure is solved under different conditions by experimental methods. Variability of a structure can be also experimentally measured by using NMR or spectroscopic techniques. Computationally, structure variability can be simulated by atomistic MD or coarse-grained models, and can also be predicted from the structure. Applications of MDs, multiple structure alignment, and flexibility prediction are shown.

Biographical Sketch

Xusi Han is currently a PhD candidate in Department of Biological Sciences at Purdue University, West Lafayette, Indiana, USA. She is also pursuing toward the M.S. degree in Applied Statistics at Purdue University. She received the B.S. degree from Minzu University of China, Beijing, China, in 2009. Her current research interests include protein global structure comparison, protein structure classification, and graph analysis for electron microscopy density maps.

Woong-Hee Shin is currently a postdoctoral researcher of the Kihara Lab in the Department of Biological Sciences at Purdue University. He received the B.Sc. in chemistry from Seoul National University, South Korea in 2008. He also received the PhD degree in chemistry in 2014 from Seoul National University. During his PhD research, he developed a flexible-receptor ligand docking program, GalaxyDock, and performed virtual ligand library screening to find active molecules of nuclear receptors. After receiving his PhD, he joined the Kihara lab in August 2014. His current research interests are development and application of computational drug discovery programs.

Charles Christoffer is currently a graduate member of the Kihara Lab at Purdue University, West Lafayette, Indiana, USA. He received the B.S. degree in Computer Science and Applied Mathematics from Purdue University in 2015. He is currently pursuing the PhD degree with the Department of Computer Science at Purdue University. His research interests include geometric data structures, computer vision, and image processing, especially their application to structural bioinformatics. Within structural bioinformatics, he is particularly interested in protein docking and structure database search.

Genki Terashi is currently a postdoctoral researcher of the Kihara Lab in the Department of Biological Sciences at Purdue University, West Lafayette, Indiana, USA. He received the B.S., M.S., and PhD degrees in Pharmaceutical Sciences from Kitasato University, Tokyo, Japan, in 2002, 2004 and 2008, respectively. His current research interests include protein structure model refinement, protein structure modelling and comparison, and protein-protein docking. Application of Machine Learning method to the structural biology is also his research interest.

Lyman Monroe is a PhD candidate in the Department of Biological Sciences at Purdue University, West Lafayette, Indiana, USA. He received the B.S. degree in Physics from Purdue University in 2012, as well as a second B.S. degree in Chemistry from Purdue University in 2013. His projects include protein structure modelling and refinement using molecular dynamics simulation.

Daisuke Kihara is a full professor in the Department of Biological Sciences and the Department of Computer Science at Purdue University, West Lafayette, Indiana, USA. He received the B.S. degree in Biochemistry from the University of Tokyo, Japan in 1994, and the M.S. and PhD degrees from Kyoto University, Japan in 1996 and 1999, respectively. He was a postdoctoral researcher with Prof. Jeffrey Skolnick at the Danforth Plant Science Center, St. Louis and at SUNY Buffalo from 1999 to 2003. He joined Purdue University as an assistant professor in 2003 and was promoted to associate professor in 2009 and to full professor in 2014. His research field is bioinformatics. His research projects include protein docking, protein tertiary structure prediction, structure- and sequence-based protein function prediction, and computational drug design. He has published over 140 research papers and book chapters. His research projects have been supported by funding from the National Institutes of Health, the National Science Foundation, the Office of the Director of National Intelligence, and industry. In 2013, he was named a University Faculty Scholar by Purdue University.

Identifying Functional Relationships Via the Annotation and Comparison of Three-Dimensional Amino Acid Arrangements in Protein Structures

Mohd Firdaus-Raih and Nur Syatila Abdul Ghani, Universiti Kebangsaan Malaysia, Bangi, Malaysia

Introduction

The primary computational approach used for assigning biological function to protein sequences is dependent on the extrapolation of function based on sequence level similarities. Although the increase in the number of sequences with annotated functions has made sequence alignment based tools highly accurate and adequate, there remains a subset of proteins that have yet to be characterized for function. In the numerous genome sequences being generated at present, many of these sequences are annotated as hypothetical proteins based on the prediction that their open reading frames can hypothetically code for a protein. Many such hypothetical proteins have been expressed, purified and had their structures determined by crystallographic methods via structural genomics approaches. This is evident in the number of proteins with uncharacterized functions that are being deposited in the Protein Data Bank (PDB) (Rose *et al.*, 2017). It is known that at levels where sequence similarity is no longer detectable, fold similarity may still exist and hence still result in similar functions. Therefore, considerable efforts have been made to determine the functions of such hypothetical proteins by characterizing their three-dimensional (3D) structures.

Although the molecular structure of a protein can be expected to reveal potential fold similarities to structures with characterized function, there are still protein structures in the PDB that do not have any fold similarities to any other characterized examples (Nadzirin and Firdaus-Raih, 2012). As a result, these proteins are still classified as having uncharacterized function despite having lost the hypothetical protein label. One approach towards identifying the potential function of such proteins would be to investigate the potential for specific arrangements of amino acids to carry out a particular chemical reaction or biological function. A common example can be seen where convergent evolution leads toward the formation of catalytic triads that share no common evolutionary history and in such cases the resultant 3D arrangement to form the triad is a requirement for catalysis to occur. In order to execute the analysis of 3D structures for such arrangements, the tools employed will have to extend beyond sequence and fold level comparisons to the level of specific 3D formations of the amino acid residues.

The availability of information regarding specific interacting residues for different modes of protein functions and interactions such as catalytic sites (Porter *et al.*, 2004), protein-DNA (Luscombe *et al.*, 2001; Selvaraj *et al.*, 2002; Angarica *et al.*, 2008; Contreras-Moreira, 2010), protein-RNA (Jones *et al.*, 2001), protein-protein (Raih *et al.*, 2005; Kinjo and Nakamura, 2010), protein-carbohydrate (Malik *et al.*, 2010) as well as other protein-ligand interactions and sites that are potential interaction surfaces such as clefts (Laskowski *et al.*, 1996), can be utilized as a database of known motifs to search against. The SIFTS database is an excellent example of a resource containing cross-referenced datasets that include residue level mappings which can in turn be deployed for use as a motifs database (Velankar *et al.*, 2013).

By integrating computational tools that are able to search at the sub-structure level or for specific residue arrangements with the prior knowledge on the function of similarly arranged residues, the user of such tools may be able to pin-point a possible line of enquiry for further investigation that may lead towards successful functional characterization of a protein of unknown function. In this article, computational methods of searching or comparing 3D level arrangements of amino acids are compared, and the approaches as well as general strategies for their use are discussed.

Background

Fold Comparisons Versus Amino Acid 3D Motif Searching

It is well known that in homologous proteins, divergence of sequence identity to even less than 30% can still result in the maintenance of a similar general fold (Chothia and Lesk, 1986). This has led to the development of numerous methods and databases specifically aimed at classifying and comparing the similarities in folding for protein 3D structures. Methods that perform structural alignments such as DALI (Holm *et al.*, 2006), FATCAT (Ye and Godzik, 2004) and VAST (Gibrat *et al.*, 1996) have long been frontline tools for the annotation of protein structures. Such fold comparison methods have proven useful even in the absence of any significant sequence similarity as demonstrated by Artymiuk *et al.* (1997) who reported that the domain folding of a then recently solved structure of adenylyl cyclase resembled the 'palm' domain of the polymerase I family of prokaryotic DNA polymerases.

However, in cases of convergent evolution, the absence of not only detectable sequence similarity, but also fold similarity, can be observed in proteins that execute generally similar mechanisms in order to carry out their functions. For proteins that have sites sharing a similar mechanistic function with others, but are unrelated in other parts of the structure, there may exist clusters of amino acids that are similarly arranged despite undetectable sequence similarity and different folding. Such similarity in 3D arrangements of amino acids in evolutionarily unrelated proteins can result in similar chemical activity or molecular function such as catalytic sites, ligand binding sites and various nucleic acid binding sites. In order to enable a structure to be annotated or

compared for such similar 3D amino acid constellations, the methods need to be able to accept a query that can be compared against 3D structure data such as those in the PDB. By developing methods that can search for such similarities, we would then be able to associate hypothetical proteins to characterized proteins as well as generate an inventory of conserved side chain arrangements and the functions that they serve.

In general, there are two approaches that can be taken to carry out searches for such tertiary motifs. One approach would be to enable the search engine or comparison program to accept an input file containing 3D structural information such as a PDB coordinate file and using that input as a query to search against a database of 3D motifs or a database of 3D structures. Another approach would be to allow a user to define or design the query that is representative of a 3D motif and using that input as a query to search against a database of 3D structures. There are now a number of programs that are able to carry out such searches and although they subscribe to the two general approaches mentioned above, the implemented algorithms between these available programs differ. In many cases, the different programs available complement each other by filling in the gaps in terms of search methodology, coverage and computational capacity. In this paper, only computer programs that carry out these types of 3D motif searches that are also available as web services and using PDB associated data are discussed (Table 1).

Fold and Sequence Independent Motifs in Protein Structures

Advances in macromolecular crystallography and high throughput molecular biology have led to numerous structural genomics projects. In Chothia (1992) reported that the number of different families was finite and may be as limited as one thousand distinct protein shapes. Therefore, as the PDB expands, it is most likely that the number of novel folds reported will not increase dramatically despite the contributions by the depositions from the structural genomics initiatives. This slow-down in the rate of growth for novel protein structural data in the PDB had been reported by Levitt (2007). As a result of the structural genomics contributions and the decrease in novel folds being discovered, concerted efforts are now being directed by many structural biology groups to target the solution of structures for proteins with unknown functions, specifically proteins that were annotated

Table 1 List of computational programs for 3D motif search

<i>Input format</i>	<i>Query type</i>	<i>Program/service</i>	<i>Search approach</i>
Input file format: PDB	Complete protein structure	COFACTOR	Identify proteins of similar fold and functional sites through global and local structural similarities (Roy <i>et al.</i> , 2012).
		eF-Seek	Search for similar binding sites in PDB based on molecular surfaces and calculation of electrostatic potentials (Kinoshita <i>et al.</i> , 2007).
		GIRAF	Identification of ligand binding sites in the PDB that are structurally similar to substructures of the query (Kinjo and Nakamura, 2007).
		MetaPocket 2.0	Identification of binding cavities using multiple computational platforms (Zhang <i>et al.</i> , 2011).
		MultiBind	Recognize common spatial patterns through multiple structural alignment of binding sites from a set of bound structures (Shulman-Peleg <i>et al.</i> , 2008).
		ProFunc	Identification of probable active sites and possible homologues in the PDB (Laskowski <i>et al.</i> , 2005).
		SPRITE	Convert a protein structure into representative pseudo-atom vectors for searching against a database of pseudo-atom vectors representing known 3D motifs and sites (Nadzirin <i>et al.</i> , 2012).
		ProBis	Compare protein surfaces and recognizes geometrically similar regions (Konc and Janezic, 2010).
		SA-Mot	Identification of structural motif from protein loop structures using structural alphabet HMM-SA (Regad <i>et al.</i> , 2010).
	Complete protein structure/ 3D motif	SuMo	Find similarity in 3D structure or substructures of proteins against ligand binding site in PDB through heuristic search of chemical group triplets (Jambon <i>et al.</i> , 2005).
		PINTS	Find recurring three-dimensional patterns of amino acids common to two sets structures by measuring the inter-residue distances (Stark <i>et al.</i> , 2003).
	3D motif	ASSAM	Convert a PDB coordinate file representing a 3D motif or arrangement into representative pseudo-atom vectors for searching against a database of pseudo-atom vectors representing structures in the PDB (Nadzirin <i>et al.</i> , 2012).
		RASMOT-3D PRO	Search a PDB file for secondary structure independent patterns or larger super secondary structure residue arrangements (Debret <i>et al.</i> , 2009).
Other	Other	IMAAAGINE	Search a user provided residue arrangement based on the distances between residues or residue types (Nadzirin <i>et al.</i> , 2013).
		PDBeMotif	Search possible binding sites and structural motifs of a protein structure, or all instances of residue pattern in the PDB (Golovin and Henrick, 2008).

Note: A listing of the fifteen web servers discussed that can search for specific 3D arrangements of amino acid residues.

as hypothetically encoding a protein that bears no sequence similarity to any proteins of known or characterized function (Eisenstein *et al.*, 2000; Cruz-Migoni *et al.*, 2011).

Once the structures of such proteins have been solved, they are typically subjected to fold similarity searching in order to determine whether the fold is already existent in the PDB. In cases where fold similarity can be attributed, there may likely be significant insights gleaned from the structure to influence the direction of further study. Nevertheless, there are numerous other protein structures that remain annotated as ‘uncharacterized’ in the PDB. A survey of the proteins annotated as ‘uncharacterized’ in the PDB revealed that there were 1084 proteins that had no similarity to any known sequence or folds at the time of the analysis as of May 2012 (Nadzirin and Firdaus-Raih, 2012). When both sequence and fold similarity options have been ruled out for inferring homologous function for a newly solved structure, an alternative option would be to investigate whether conserved 3D motifs that constitute catalytic and binding sites could be identified despite the absence of detectable sequence and fold similarity. The programs ProFunc (Laskowski *et al.*, 2005), GIRAF (Kinjo and Nakamura, 2009), PINTS (Stark *et al.*, 2003), SA-Mot (Regad *et al.*, 2010) and SPRITE (Nadzirin *et al.*, 2012) (Table 1) are capable of identifying such 3D motifs. These programs approach a search using different methodologies and at present there is no single all capable program. Instead, they can be used collectively to complement each other where a gap in the capacity of one program is taken up by other programs. Another factor for consideration is the fact that these programs search different databases. As a result, a user may need to run multiple searches to attain coverage of all the relevant databases used and thus increasing the possibility of retrieving a significant hit.

Systems and/or Applications

In this article, we assess and compare the utility of fifteen different computer programs for structural analysis (Table 1), particularly those that can identify specific 3D arrangements of the amino acid residues and are also accessible to users as a web service. We also evaluate their accuracy in different scenarios and present a strategy for the users on how to potentially analyse structures with uncharacterized functions via these tools. Undoubtedly, some programs may even perform better than the ones we have evaluated here, however, if they are not freely available and accessible via a web interface, they were not incorporated into this article.

Input Formats

With the exception of the IMAAAGINE server, all the other services accept a PDB formatted coordinate file as input. Both the IMAAAGINE and PDBeMotif servers allow for a user-defined pattern of amino acids provided as input via the web interface. The IMAAAGINE server requires that the user conceptualize an amino acid arrangement that is defined by distances between the residues in the pattern. The PDBeMotif server additionally provides comprehensive analyses of sequence, 3D motifs, and the ligand environment that can be provided as input via the web interface.

Output and Average Time for Computations

The fifteen servers assessed typically take from approximately a minute up to several hours for a calculation involving a protein structure that we had used as a test input. However, this rather large variation was expected due to the calculation times depending on factors that include, but are not limited to input size, the number of jobs being computed or queued on the servers and the different algorithms employed by the services. Most servers returned a tabulated summary of hits ranked by local structural similarity scores and downloadable results, while some servers also facilitated or allowed for the visualization of matched 3D arrangements (Table 2).

Analysis and Assessment

Searching Motifs/Sites Databases With a Structure Query

In the case of many protein structures that have no detectable sequence similarity, a fold similarity search using DALI may be sufficient for identifying structural homology. However, even in such cases, comparing specific clusters of amino acids within the structure can yield further insights regarding the specific activity or interaction partners of the protein. A simple step by step strategy that can be adopted after an initial fold level similarity search would be to submit the structure of interest to either selected or all of the services listed in Table 1 that are able to process a complete PDB structure as a search query. In selecting specific services, one should consider the capacities and database scope for the programs used. For example, the database attached to SPRITE is drawn from motifs in the catalytic site atlas (CSA) (Porter *et al.*, 2004), the ProCarb dataset (Malik *et al.*, 2010), the 3D-Footprint dataset and those manually extracted from literature. The ProBis service works by comparing protein surfaces and identifying geometrically similar regions thus making it less dependent on requiring prior knowledge regarding a motif such as SPRITE (Konc and Janezic, 2010) (Table 3).

When using predictive and/or computational methods, it is generally prudent to use several programs that employ different approaches by selecting representatives or highly used programs from each methodology class. The results from these various programs can then be compared and in cases where there is a clear agreement, those particular results can be further investigated. Nevertheless, the problem

Table 3 Relevant hits for query of BPSL1549 protein

Prediction	Server	Results
Homologs	COFACTOR	Returned 10 chain homologs from fold comparison, which includes CNF1-C, and several uncharacterized proteins. Gene Ontology (GO) term prediction for Biological Process (BP) resulted with 'arginine biosynthetic process'.
	ProFunc	Returned 10 PDB chains with similar fold, including chemotaxis deamidase and several uncharacterized proteins. The server predicts possible function of BPSL1549 in the regulation of helicase activity and molecular function, based on GO prediction for Biological Process (BP).
3D motif	MetaPocket 2.0	Resulted with top 3 pocket sites clustered from sites generated by 8 prediction tools, where each consists of large number of residues.
	ProBis	Returned 100 similar proteins with aligned residues from structural superposition, which include a putative ABC transporter (PDB chain: 4pe6A) with 11 aligned residues. The server predicted putative ligands of BPSL1549 protein for small molecules, proteins and ions. The server also predicted a binding site for Bromide ion, similarly reported by PDBeMotif.
	COFACTOR	Predicted PDB chains with similar binding sites for adenosine monophosphate, cerulenin, magnesium and sodium ions.
	GIRAF	Returned 100 structures with similar 3D templates, ranked by normalized GIRAF score, where top five hits consist of more than 10 aligned residues from structural superposition.
	PDBeMotif	The server reported matched small 3D motifs and a binding site for bromide ions within 5.0Å to the ligand.
	ProFunc	The server returned several hits from reverse template search that mapped to auto-generated templates from BPSL1549 protein itself, which include templates from several keap proteins.
	Ef-seek	Returned predicted ligand binding sites from matched PDB structures ranked by Z-score, which include binding sites for PDB ligand code of PEF, BCR, STE, and LIL.
	SA-mot	Predicted a functional candidate motif consisting of a fragment of seven residues that are continuous in sequence.
	SPRITE	Returned proteins with similar 3D template as BPSL1549 ranked by RMSD value. The hits include a chemotaxis methylation protein (2f9zD) where a residue arrangement of Thr88, Cys94, and His106 from BPSL1549 protein matches Thr21, Cys27, and His44 residues from the chemotaxis methylation protein.
	SuMo	Returned matching ligand binding sites sorted by site volume, which include binding sites for PDB ligand codes of ACT, PO4, MLI, SF4, and GLC.

Note: A listing of the results returned by the different services when the BPSL1549/3tu8 protein structure was used as a query to identify 3D motifs present in the structure.

should not be approached using a one size fits all solution and as such, other results may also warrant further investigation. For example, if two seemingly non-homologous structures that share no detectable sequence identity were to have 3D motifs that could be superimposed after using a 3D site search program such as SPRITE, PROBis and PINTS, their sequences can be manually aligned using the superposed arrangement as a reference point. The decision to proceed further with a particular motif can take into account a number of factors that are determined by the user depending on their own interests and motivation. The residues that match to sites from a database can be further extracted and submitted as a query for searching against a database of PDB structures. Computer programs such as RASMOT-3D Pro (Debret *et al.*, 2009) and ASSAM (Nadzirin *et al.*, 2012) are able to execute such queries.

Searching a Structure Database Using a 3D Motif Query

The obvious limitation of using a complete structure to query a motif database is the requirement of prior knowledge for the motifs while the clear advantage would be that such motifs would probably be well characterized with perhaps attached experimental annotations. Although it would be useful to be able to annotate a newly solved protein structure for known sites, there are situations where no prior knowledge exists of a motif that can be found for that query. In such a scenario, a visual examination or surface analysis of the structure may provide incipient information on potentially functional residues. Once the residues of interest have been identified, they can then be provided as queries to search for structures where similar arrangements occur. This approach does not require these sites to have been previously identified or annotated. If similar arrangements are found, contextual references and comparisons can then be made for the structures where the arrangements are present. In comparison to methods that use a whole structure input, there are fewer programs that are able to receive a pattern input for searching against a database of 3D structures. Two such services that are available on the web are ASSAM (Nadzirin *et al.*, 2012) and RASMOT-3D Pro (Debret *et al.*, 2009).

Although the RASMOT-3D Pro (Debret *et al.*, 2009) and ASSAM (Nadzirin *et al.*, 2012) programs essentially carry out the same type of search, where a motif in PDB format can be submitted as a query, the representation system used for the amino acids in 3D space are different. In the RASMOT-3D Pro program, the C α and C β positions are used to represent a residue (Debret *et al.*, 2009); while in ASSAM, the side chain positions are represented using pseudo-atom vectors (Nadzirin *et al.*, 2012). This has been demonstrated to result in a different retrieval list because an overlapping side chain position may have extended from C α atoms

Fig. 1 Superposition of Arg-Glu-Arg-Glu patterns found in two different protein structures. The superposition of an Arg-Glu-Arg-Glu pattern consisting of two arginine and two glutamic acid from a sucrose-specific porin (PDBID: 1a0s) (green) and a DNA polymerase (PDBID: 2atq) (blue) where the side chains overlap although the C α atoms do not. The atoms are shown in ball-and-stick representation, C α atoms as spheres, and all other atoms in stick representation.

that do not overlap (Nadzirin *et al.*, 2012) (Fig. 1). Therefore, a side chain based representation can be useful in cases of convergent evolution where the positions of the side chains remain conserved in 3D space in order to effect a specific chemical outcome such as catalysis. RASMOT-3D Pro offers the user an option of searching for the query motif in a set of up to 10 user provided structures; ASSAM only allows for pre-set database options.

Discovery of Novel Motifs Present Only in a Structural Context

With the exception of PDBeMotif (Golovin and Henrick, 2008) and IMAAAGINE (Nadzirin *et al.*, 2013), other programs listed in Table 1 have a limitation where they require prior knowledge of the 3D motifs available for searching against, or the coordinates of a specific 3D arrangement to be provided as a search query. PDBeMotif and IMAAAGINE can carry out PDB searches using a query where the user can determine the type of amino acid and specify the distances between them without knowing how they are exactly arranged in 3D space. This overcomes the need for the user to define a specific pattern such as for several of the other previously listed programs in Table 1. Due to the use of pre-computed distance information within each single protein chain in a PDB file for its database, PDBeMotif only finds sub-structures if all the amino acids are in the same chain.

The IMAAAGINE program was engineered to carry out searches for a query that was designed by the user although it does not provide extensive key word querying capabilities such as in PDBeMotif. The IMAAAGINE queries can be very generic in nature such as: “are there arrangements where the side chain of an aspartic acid is surrounded by four hydrophobic residues?” (Fig. 2). The advantages of such a search capability are: (i) the ability to search for conserved 3D arrangements that are novel; and (ii) the ability to identify motifs present only in a structural context that are not detectable at the sequence level. This differs from the capability provided by other programs, such as RASMOT-3D Pro, ASSAM and SPRITE, that search a database of PDB structures for motifs. In these programs, prior knowledge of the motif is required to be provided as a PDB formatted input. However, in the case of IMAAAGINE, the user can approach a query based on a biochemical understanding of how a cluster of amino acids can be theoretically arranged in order to achieve a certain function. Since no prior knowledge is required regarding an exact arrangement of the amino acids to be used as a query, this allows for a broader search that may in turn retrieve hits that were not originally intended by the user.

Due to its flexible query input, the IMAAAGINE program has the capacity to retrieve highly conserved arrangements that may have been below the radar of standard structural analysis and annotation approaches. Furthermore, an IMAAAGINE search is not restricted by the location of residues to a particular chain or monomer in a multimeric assembly since it considers only the relative positions of a side chain representation to others based on calculated distances. The results of an IMAAAGINE search can therefore uncover arrangements, that if found to be highly conserved, can then be considered a novel 3D motif. Such motifs may prove to be functionally relevant although its conservation is identifiable only from a structural context and can therefore be not obvious from a purely sequence analysis approach. In the next section, case studies are presented that compare and illustrate the differences of the webserver discussed.

Illustrative Examples and Case Studies

Detection of 3D Motif in Protein Structure – Possible Functional Annotation of a Hypothetical Protein

The protein sequence encoded by the ORF *bps1549*, from the genome of the pathogen *Burkholderia pseudomallei*, was originally annotated as a hypothetical protein (Holden *et al.*, 2004) with no detectable sequence similarity to any sequences other than

Fig. 2 An example of an IMAAAGINE query for a user-defined arrangement of amino acids. (A) This IMAAAGINE input example shows a search for an aspartic acid (R5) surrounded by four hydrophobic residues within the distance of 3.0 Å (R1-R4). (B) The retrieved overlapping side chains for the search is shown from the superposition of 3D patterns consisting of four alanine surrounding an aspartic acid from a 4-hydroxyphenylpyruvate dioxygenase (PDBID: 1sp8) and a tyrosyl-tRNA synthetase (PDBID: 2jan).

obvious homologs of itself within the Burkholderia genus. The crystallographic structure for BPSL1549 was then acquired (Cruz-Migoni *et al.*, 2011) (Fig. 3(A)) and fold comparisons using DALI revealed fold similarity to the catalytic domain of cytotoxic necrotizing factor 1 (CNF1-C) from *Escherichia coli* (PDB ID: 1hq0), with a Z-score of 9.5 and a chemotaxis deamidase from *Thermotoga maritima* (PDB ID: 2f9z) with a Z-score of 5.9 (Fig. 3(B)).

The structure of BPSL1549 (PDB ID: 3tu8) consists of a beta-sandwich fold surrounded by α -helices and loops (Fig. 3(A)) as similarly observed in the catalytic domain of CNF1-C (Cruz-Migoni *et al.*, 2011), an enzyme catalyzing glutamine deamidation that results in the alteration of the host cell actin cytoskeleton. This provided a clue that BPSL1549 may be involved in a similar activity and was compounded by the fact that a SPRITE search identified similarly arranged residues consisting of Thr88, Cys94 and His106 in BPSL1549 that matched the CNF1-C catalytic triad consisting of Val833, Cys866 and His881, where the cysteine and histidine are conserved among such toxins and required for deamidation of glutamine (Buetow *et al.*, 2001; Cruz-Migoni *et al.*, 2011) (Fig. 3(C)). The SPRITE search also returned a similar arrangement of Thr-Cys-His shared with a chemotaxis deamidase from *T. maritima* (PDB ID: 2f9z) at an RMSD value of 0.49, thus signifying the possible role of BPSL1549 and the importance of such arrangement in glutamine deamidation. A search on SuMo web server on the other hand, returned a similar arrangement of Thr-His-Val shared between BLF1 and D-xylose isomerase from *Streptomyces rubiginosus* (PDB IDs: 3kbn and 1xic) (Kovalevsky *et al.*, 2011; Carrell *et al.*, 1994).

COFACTOR and ProFunc were used to search for possible homologs of BPSL1549 and both servers returned a different set of similar structures and GO terms prediction. The COFACTOR server proposed a possible role for BPSL1549 in glutamate N-acetyltransferase activity for Molecular Function (MF) and arginine biosynthesis for Biological Process (BP) prediction, while ProFunc predicted the function of BLF1 to be involved in regulation of helicase activity and molecular function for Biological Process (BP) prediction. The information from different servers can prove useful collectively (Fig. 3(D)) as it was ultimately proven that BPSL1549 is a deamidase that converts Gln to Glu on its target molecule, the translation initiation factor eIF4A which has a

Fig. 3 Detection of 3D motif using various 3D motif searching methods. (A) Ribbon representation of a crystal structure of BPSL1549 from *Burkholderia pseudomallei* (PDBID: 3tu8). The residues binding the bromide ion (in red) are displayed as blue sticks. (B) The BPSL1549 (PDBID: 3tu8) in tan color and the CNF1-C (PDBID: 1hq0) in light blue color are shown in ribbon representation, after the superposition. (C) Superposition of catalytic triad residues from chemotaxis deamidase (PDBID: 2f9z) (red) and CNF1-C (PDBID: 1hq0) (magenta) to BPSL1549 (PDBID: 3tu8) (cyan). (D) A graphical representation displaying the BPSL1549/3tu8 structure with the output from various web servers (in different colors) mapped onto it in molecular surface representation.

helicase function (Cruz-Migoni *et al.*, 2011). This resulted in the renaming of BPSL1549 to *Burkholderia* lethal factor 1 (BLF1) due to it being the first confirmed toxin for *B. pseudomallei*. Similar residues for the bromine ligand binding site was detected by ProBis and PDBeMotif – Gln145, Arg142, and Asn168 with no other protein sharing a similar residue arrangement. Table 2 summarizes the findings when BLF1 (PDB ID: 3tu8) was used as the search query.

Detection of Arg-Glu-Arg-Glu Query Motif in Database of PDB Structures

It is also a common approach to visualize a structure using the various molecular graphics software available in order to glean some insights into the function of a newly solved structure. Through such visual inspections, specific residue arrangements of interest can be identified – for example arrangements that may have potential as a catalytic site or ligand binding site. It then becomes useful to identify whether such similar residue arrangements exist in other structures and whether there are known functions associated with them. To demonstrate this, a four residue arrangement consisting of Arg, Glu, Arg, Glu (RERE – Fig. 4(A)) from a *Salmonella typhimurium* sucrose-specific porin (PDB ID: 1a0s) was extracted from the main PDB file and submitted as an ASSAM search. The 1a0s structure was classified as a LamB porin domain (PFAM accession: PF02264) in PFAM and contains 16 antiparallel strands with several binding sites for glycosyl groups along the channel involved in sugar transport (Forst *et al.*, 1998) (Fig. 4(A)).

The ASSAM search retrieved a RERE arrangement in a fusion protein consisting of a DNA polymerase with a single-stranded DNA binding protein (PDB ID: 2atq; Fig. 4(B)). The R437, E439, R441, E480 side-chains from 1a0s are similarly arranged spatially with R751, E747, R750 E755 from 2atq (Fig. 4). The 2atq structure consists of an N-terminal domain that allows binding of T4/

Fig. 4 Detection of Arg-Glu-Arg-Glu patterns in distinct protein structures. (A) The pattern consisting of two arginine and two glutamic acid (RERE) in a sucrose-specific porin (PDBID: 1a0s) is depicted as sticks (green) and magnified on the right panel. (B) The same RERE arrangement in a DNA-polymerase (PDBID: 2atq) depicted as sticks (light blue) and magnified in the right panel.

RB69 single-stranded DNA binding protein to single-stranded DNA, a C-terminal domain that mediates the interaction with accessory proteins and a DNA-binding domain that binds to single-stranded DNA (Sun *et al.*, 2006) (Fig. 4(B)). It is clear that the two structures do not share any similar sequence or fold despite the fact that these four side-chains form a restricted spatial arrangement present in both structures that can be 3-dimensionally superimposed (Fig. 1). From the superpositions, it is evident that the overlap occurs at the side-chain positions and not at the alpha-carbon positions thus making them potentially significant in terms of the functional chemistry for both molecules. However, in cases when conservation is at the core back-bone level with variations in the spatial arrangements of the side-chain leading to slightly different chemistry – such as different target ligands for the site, then the RASMOT-3D Pro server would be a more suitable option to search with.

Discussions and Future Directions

The capacity to infer function by associating the chemical capacity or functional potential of 3D motifs is an important step towards the computational annotation and ultimate functional characterization of the many structures of proteins with uncharacterized functions. Nevertheless, most computational function annotation is still carried out at the primary structure or amino acid sequence level. While many of the programs discussed in this article may be able to make associations between conserved 3D amino acid arrangements in proteins of unrelated sequences and folds, there is still a need for novel 3D motifs to be identified using mainstream sequence analysis, especially 3D motifs that are functionally relevant only in a structural context.

As an example, a 3D interface between three chains of the same sequence that consists of a single residue, each at the interface, such as histidine, can be considered a three histidine tertiary motif. However, such a 3D motif will only be represented by a single residue and position in the sequence. This therefore necessitates the development of programs that are able to bridge the gap and identify such single residue motifs perhaps via machine learning approaches using the physico-chemical profiles of the surrounding residues once they are identified as structurally contextual motifs. The information from such investigations can therefore be incorporated back into sequence level analysis thus allowing for accurate identification of motifs that are relevant only in a structural context.

Closing Remarks

The ability to search for similar 3D arrangements of amino acids is of great utility in the post-genomics era, especially in light of the many structural genomics initiatives. However, there is no clear one-stop service or one size fits all solution at present. Despite this, expert use of the available tools and services have been proven as useful means of providing insights towards a line of enquiry that can ultimately enable the functions of uncharacterized proteins to be successfully determined.

Introduction

Proteins are one of the most important building blocks of the body, and are comprised of 20 different amino acids. They display a wide variety of functions including structural, catalytic, sensory, motility, immune response, transport, and many more. Owing to such diverse functions, proteins have attracted a lot of attention in the fields of agriculture, therapeutics, and industry. Protein engineering, in general, involves either synthesis of new proteins or alteration of existing protein structure and sequence in order to achieve desired functions. It aims at improving catalytic properties, stability (thermal, pH, solvent), specificity, and yield of proteins, and finds wide applications in the fields of medicine, nanotechnology, biopolymer production, detergent, and food industry.

In the early 1980s, the advancement in the field of recombinant DNA technology enabled the engineering of proteins that was mediated via changes in the proteins' amino acid sequence (Ulmer, 1983). Subsequently several other methods were developed for engineering proteins including random mutagenesis, site directed mutagenesis, evolutionary methods, domain shuffling, and others. Subtilisins in detergent industry; tissue plasminogen activator (tPA) in heart attack and stroke treatment; Humalog, Novolog, and Apidra (engineered insulin) for diabetes treatment; and engineered amylases and lipases used in food industry are some of the examples of commercially available engineered proteins (Walsh, 2007; Turanli-Yildiz *et al.*, 2012). Despite being so promising, widespread application of protein engineering techniques was limited owing to labor-intensive and time-consuming protocols, and use of large amount of resources.

In the past few decades, a tremendous revolution in computational protein engineering has helped protein manipulation in overcoming the above mentioned barriers. Novel protein design algorithms, advancement in structural bioinformatics, molecular force fields, and availability of immense information regarding 3D protein structure in databases like Protein Data Bank have revolutionized the field of computational protein engineering. Computational protein designing broadly focuses on (1) generation of *de novo* amino acid sequences that can adopt stable 3D structure, or modification of the existing scaffold to improve the stability of the protein in non-native environment, and (2) evolving newer functions in proteins by harnessing information from known crystal structures (Alvizo and Mayo, 2008). A schematic representation of common computational protein engineering approaches is illustrated in Fig. 1. These include (1) *de novo* protein modeling, (2) rational designing of proteins based on existing structural templates, and (3) statistical modeling. *De novo* protein structure prediction methods make use of general protein folding principles and energetics (deduced from native structures) to assign tertiary structures to the sequence of amino acids. It is generally used for the sequences with no close homologs with experimentally solved structures. *De novo* methods involve vast computations and hence are so far limited to small proteins only. In rational designing approach, rather than attempting to start from scratch, the experimentally known protein structures can be utilized as templates to build on. This approach at least ensures the *in vivo* stability of the engineered proteins. Here, the rationale is to look for the part of protein that is less important for proper folding, and remodel it to introduce new functionality. Statistical modeling or the data-driven approaches are used to infer relationships between protein sequence, structure, and function from experimental data. These learning algorithms are based on the fact that the amino acids comprising the proteins encode their chemical properties and govern their biological functions. These statistical models are capable of capturing the global behavior of proteins, are not biased, and therefore can be used to make predictions for novel sequences.

Some of the commonly used computational algorithms and approaches for aiding in protein engineering include dead-end elimination (DEE), molecular dynamics simulations, Monte Carlo simulated annealing, and genetic algorithms (Park *et al.*, 2004; Floudas *et al.*, 2006). Many tools are available to computationally evaluate the effect of changes made in the protein structure. For example, SCHEMA is a tool that calculates DNA recombination mediated disruption in terms of the *E* value (where *E* is the average disruption of residue contact). The engineered protein with low *E* value is taken further to achieve functionally active modified protein that is less identical to the parent protein (Meyer *et al.*, 2003). Protein Sequence Activity Relationships (ProSAR) is another tool that can sort diverse mutations by predicting their effect on desired protein activity and thus providing mutants that are highly improved in comparison to the wild-type protein (Fox *et al.*, 2007). Rosetta, the most commonly used computational method, aims at creating new biocatalysts from existing template structure, taking into account an active site's quantum mechanical parameters and carrying out design around the reaction's transition state (Rothlisberger *et al.*, 2008; Der *et al.*, 2013). A few other computational protein design tools include FoldX, FlexPreD, and Iterative Protein Redesign and Optimization (IPRO) (Li *et al.*, 2012; Verma *et al.*, 2012; Saraf *et al.*, 2006). Table 1 lists some of these commonly used tools with their brief description.

A large number of successful stories of protein engineering are reported in the literature. The structures predicted by computational methods have been shown to have atomic level accuracy with respect to NMR structure of protein (Murphy *et al.*, 2015). Recently, a peptide design was reported that mimicked the N-trimer region of the GP2 fusion protein of the Ebola virus, which is a potential target for drugs (Clinton *et al.*, 2015).

Fig. 1 A schematic representation of the common computational protein engineering approaches: *de novo* designing, protein engineering based on the existing templates, and statistical modeling.

The available computational methods are robust and help in decoding the information hidden in the sequences for protein engineering. Most of the biochemical processes depend upon the specificity of interacting proteins in a crowded cellular environment. Also the stability of the structured proteins influences the formation of functional complexes to initiate the biological response. Thus, the efficiency of any such interaction is primarily governed by two factors: stability and specificity. So, rational re-engineering of proteins must involve improvement in stability, and reduction in affinity for competing binders. Maintaining a balance between the stability and specificity has always remained a challenging task and holds potential implications for the development of newer tools based on existing biological systems for varied applications. Here, successful stories of proteins that have been engineered using various computational approaches have been discussed, with a focus on three important aspects: protein specificity, stability, and novel functionality.

Applications of Computational Protein Engineering

Alteration in the Specificity of Macromolecules by Structural Modifications

The function of nearly all proteins depends on their ability to bind other molecules, or ligands, with a high degree of specificity. High specificity in proteins makes them important players for many industrial and therapeutic applications. Specificity, in simple words, can be described as the ability of a protein to bind one molecule in preference to other molecules. In this section, we have

Table 1 Computational tools for engineering of proteins

Protein engineering approach	Resource	Description
De novo designing	PyRosetta Toolkit (Adolf-Bryfogle and Dunbrack, 2013)	Graphical user interface for <i>de novo</i> designing of proteins using Rosetta toolkit
	EvoDesign (Mitra <i>et al.</i> , 2013)	Structure and evolutionary profile based search to design proteins
	ORBIT (Dahiyat and Mayo, 1996)	Uses rotamer description of side chains to predict the most optimal geometry for any amino acid sequence from vast number of possible solutions
	POCKETOPTIMIZER (Stiel <i>et al.</i> , 2016)	Optimizes protein-binding site for new ligand
	SABER (Nosrati and Houk, 2012)	Selection of active/binding sites for enzyme redesign (SABER). Designs new active/binding site by identifying protein active sites with similar arrangement of catalytic residues from PDB
	DEEPer (Hallen <i>et al.</i> , 2013)	Algorithm for protein engineering through generation of ensemble of protein backbone and side chain flexibility
Structure or template based designing	DEZYMER (Hellings and Richards, 1991)	Utilizes backbone information to identify positions of residues to be modified for incorporation of new binding site
	CAVER (Chovancova <i>et al.</i> , 2012)	Uses molecular dynamics simulation trajectories to identify tunnel and channel characteristics from large ensemble of protein conformations. This information can be utilized to engineer phenomena of molecular transport, enzymatic catalysis, and molecular recognition
	Metal Search (Clarke and Yuan, 1995)	Uses backbone coordinates to identify cluster of residues that can form tetrahedral metal binding site upon replacement with Cys or His
	FlexPred (Kuznetsov and McDuffie, 2008)	Web server to predict protein flexibility by recognizing residues involved in conformational switches
Statistical modeling	FoldX (Schymkowitz <i>et al.</i> , 2005)	An empirical force-field based method designed to check the effect of mutations on stability and folding dynamics of proteins
	AUTO-MUTE (Masso and Vaisman, 2010)	Web server based on machine learning algorithms designed for predicting effect of mutations on stability of proteins
	iPTREE-STAB (Huang <i>et al.</i> , 2007)	Utilizes decision tree algorithm to discriminate between stabilizing and destabilizing mutations; employs regression and classification tree algorithm for prediction of effect of mutations on protein stability
	MuD (Wainreb <i>et al.</i> , 2010)	Mutation Detector (MuD): utilizes Random Forest based algorithm to discriminate between functionally neutral and non-neutral mutations. It utilizes structure and sequence information to predict the effect of mutations on protein function
	PEAT-SA (Johnston <i>et al.</i> , 2011)	Empirical based method to predict the effect of mutation on ligand affinity, <i>pKa</i> values and stability of protein

discussed some examples where computational approaches have been used to enhance the specificity of the proteins for their successful diverse applications.

Computational design of zinc finger proteins for specific binding to DNA sequences

Zinc finger nucleases (ZFNs) are promising genome engineering tools having the potential to edit DNA at the molecular level, thereby paving the way for many biological applications. These chimeric proteins are made up of two domains, one that recognizes specific DNA sequence within the complete genome and the other is a non-specific endonuclease domain that helps in introducing a double stranded break in the target sequence. The versatility of the ZFNs in the field of targeted genome editing is attributed to its DNA binding domain, which is made up of three zinc finger (ZF) motifs linked using short spacer sequences (Urnov *et al.*, 2005).

These ZF proteins comprise the largest family of transcription factors in eukaryotes. Each ZF motif contains amino acids folded into a $\beta\beta\alpha$ -structure. Extensive structural studies revealed that the modular structure remains highly conserved and the specificity of these factors toward their target DNA relies only on four amino acids, positioned at -1 , 2 , 3 , and 6 residues with respect to the start of alpha helix (Elrod-Erickson *et al.*, 1998; Wolfe *et al.*, 2000; Pabo *et al.*, 2001). Soon, it was realized that these positions can be altered artificially for changing the binding specificity of these motifs toward some other sequences. Knowledge of ZF motifs with the ability to recognize all possible DNA codons thus became a prime objective of the scientific community to gain the power for constructing artificial ZFPs for the purpose of genome manipulation for therapeutic advantages.

Experimental techniques for engineering ZF proteins by rational designing or selection from large libraries, despite being useful, were time consuming, expensive, laborious, and not accessible in academic settings (Beerli and Barbas, 2002; Greisman and Pabo, 1997). Also, randomization of all 20 amino acids at essential DNA contact positions even in three finger ZF proteins can result in an enormously huge number of possibilities that become impossible to handle experimentally. Therefore, only partial libraries could be constructed by restricting the substitution at variable sites with some key amino acid residues. Thus, one possible solution was to computationally design ZF proteins using screening or prediction algorithms.

Construction of the first non-natural ZF motif using computational approach was first reported in 1997 (Dahiyat and Mayo, 1997). A virtual combinatorial library consisting of 1.9×10^{27} amino acid sequences was constructed. This library size was reported to be 15 times larger than the random libraries obtained by experimental approaches. The size of possibilities further increased to 1.1×10^{62} by explicitly considering the rotamers of each possible amino acid at each possible position. DEE algorithm was used to find globally optimal sequences in their optimal conformations. The library was screened using an algorithm designed on the basis of physiochemical potential functions and stereochemical constraints. The structure of top ranking sequence hit was solved using nuclear magnetic resonance spectroscopy and was found to be well-ordered and in agreement with the design target structure, Zif-268. This study demonstrated the potential of computational techniques for searching huge combinatorial libraries, essential for designing novel proteins with high specificity (Dahiyat and Mayo, 1997).

Consequently, many prediction tools were developed based on the knowledge gained from the growing structural information on ZF proteins. These tools can basically be divided into two categories: (1) tools developed using experimental sequence- or structure-based data, and (2) tools simulating the biochemical interactions between ZF protein and its target DNA and estimating the specificity of binding (Grover *et al.*, 2010). Here, we briefly discuss a few tools to give an insight to the approach these tools use for computational design of ZF proteins. *Zinc Finger Tools* is a web-based utility that makes use of 49 different helices that can recognize 16 GNN, 15 ANN, 15 CNN, and 3 TNN DNA triplets. The search tool looks for all possible target sites (adjacent or interspaced) formed by any of these DNA triplets on either strand. It also reports the specificity of the ZF protein predicted using these domains from the results of a multi-target ELISA specificity assay carried out for individual ZF. Apart from predicting ZF proteins for a given sequence, the tool can also predict the probable binding site for a given ZF protein (Mandell and Barbas, 2006). Further, along with the information of the binders (i.e., known examples of high affinity ZFs and their corresponding targets), weak and non-binders were used in the development of another tool. This predicts the most optimal ZF proteins for a given DNA sequence using support vector machines (Persikov *et al.*, 2009). *Zif-Predict* is a sequence-based tool employing artificial neural networks for prediction of ZF proteins for the input nucleotide sequence. An advantage of this tool is that it takes into account the binding preference of one amino acid in the presence of another in its neighborhood, called the synergistic mode of binding (Molparia *et al.*, 2010). Another addition to this league is *Zif-Predict Interfacial Hydrogen Bond Energy (IHBE)* that uses hydrogen bond energies between amino acid residues and nucleotides to predict the highest affinity ZF proteins for the user-input DNA. This is carried out by using energies calculated for all possible combinations of triplets and ZFs with different amino acids at 4 crucial positions ($-1, +2, +3, +6$), thus covering the complete interaction sample set (Dutta *et al.*, 2016b). *ZifNN* is a tool different from the ones mentioned above. It does not depend upon the experimental data, rather uses an *in silico* derived data set of 50 three-dimensional ZF protein-DNA complexes and the estimation of hydrogen bond energies. The predictions are made using neural network models (Dutta *et al.*, 2016a). In addition to this, attempts were also made to improve the *in silico* modeling of ZF protein-DNA docked complexes using HADDOCK (Chou *et al.*, 2010). The number of sequences that can be targeted using engineered ZF proteins can be tremendously increased by designing ZF motifs for nearby but not contiguous regions in DNA. For this, a linker with appropriate length that can help in skipping the nucleotides not to be targeted while helping the next motif to correctly align with the DNA triplet is designed. A computational model has been developed for structure-based design of protein linkers for ZFNs that can skip up to 10 bp between adjacent ZF, recognized DNA triplet in the target genomic sequence (Anand *et al.*, 2013). All these efforts have taken the computational design of ZF proteins to the next level.

Structure-based computational engineering of a therapeutic antibody for improving its binding affinity

High specificity and affinity of antibodies are routinely being exploited for therapeutic and industrial purposes. These molecules are an excellent choice for fabricating diagnostic kits and biosensors.

Antibody-antigen complexes display an intense network of interactions involving multiple non-covalent bonds, making it difficult to quantify these interactions at the molecular and atomic levels. However, advancement in computational power and understanding of biological systems has led to the development of force-field parameters that can help in simulating these systems *in silico* (Barderas *et al.*, 2008; Park and Jeon, 2011). Here, we have discussed a recent report where structure-based computational techniques have been used to improve the biotherapeutic potential of 11K2 antibody (Kiyoshi *et al.*, 2014). The main objective of the study was to increase the binding affinity of 11K2 for its target antigen, monocyte chemotactic protein-1 (MCP-1). MCP-1 is a key player in many inflammatory diseases like arteriosclerosis, allergy, and rheumatoid arthritis. Knowledge gained from the crystal structure of K2-MCP-1 complex (PDB ID: 2BDN) suggested that the binding affinity of the antibody can further be increased by optimizing the complementarity determining region (CDR) of the variable domain of the light chain (VL). The interaction surface between the CDR of the VL and MCP-1 was found to be much smaller than that of the CDR of the variable domain of the heavy chain (VH) (Kiyoshi *et al.*, 2014).

Firstly, the 62 amino acids forming the CDR of 11K2 were mutated *in silico* with another 19 possible amino acids to generate a virtual library of 1178 mutants of 11K2. For each mutation, 100 randomized models were generated using MODELLER, Discovery

Studio Suite. Each model was further optimized by using a combination of simulated annealing and molecular mechanics minimization. Similarly, 1000 structures for the wild-type Ab were also generated to be considered as reference. The mutants with more favorable energy of interaction than the wild-type 11K2 were then selected for *in vitro* examination. It was observed that the selected candidates were the ones with substitution by a charged residue (Arg, Lys, Glu, or Asp). The technique of surface plasmon resonance spectroscopy was then used to calculate the kinetic rate constants of the binding of wild-type 11K2 and engineered single-mutants to immobilized MCP-1. The enhanced affinity of the new models was attributed to slower dissociation rate constants rather than faster association rate constants (Kiyoshi *et al.*, 2014). This structure based computational engineering of therapeutic antibody led to approximately 5-fold increase in affinity of Ab for its target antigen and hence strongly reflects upon the potential of computational protein engineering in the coming era (Kiyoshi *et al.*, 2014).

Computational approaches for studying the dynamics of CRISPR-Cas9 system and predicting their binding specificity

CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats) system has become a sensational genome editing technology in recent days. This system consists of two components: a guide RNA and a Cas9 (CRISPR associated protein 9) nuclease. The 5' end of guide RNA contains the 20-nucleotide stretch complementary to the region of interest in genome followed by a protospacer adjacent motif. This CRISPR RNA drives the Cas9 nuclease to this complementary site in DNA and guides it to introduce a double strand break (DSB) in that region. Hence, Cas9 can be directed to produce DSB in any region in the genomic DNA that is of the form N(20)-NGG by designing guide RNA with the complementary sequence of target (Hsu *et al.*, 2014; Doudna and Charpentier, 2014; Ran *et al.*, 2013b). Designing the experiment using CRISPR is simple and promising; however the major drawback that is limiting its widespread use for industrial and therapeutic purposes is its off-target activity (Tsai *et al.*, 2015). The guide RNA-Cas9 complex can bind and cleave other unintended regions in the genome having sequence similarity with the target region. A major part of published studies in CRISPR is thus aimed at understanding the factors governing and improving the specificity of the system (Doudna and Charpentier, 2014; Hsu *et al.*, 2014; Chéron *et al.*, 2017; Ran *et al.*, 2013b).

Modifications to the actual system were designed to tackle this problem of off-target activity. The strategy of paired nickases was developed, which reduces the off-target activity by 50–1500 without affecting the on-target activity (Shen *et al.*, 2014; Ran *et al.*, 2013a). fCas9 is another strategy similar to paired nickases produced by fusing inactive dCas9 (Cas9 that lacks endonuclease activity) with one of the two monomers of *FokI* endonuclease. Hence, to make a DSB, fusion of two fCas9 monomers is required. Each monomer is complexed with a guide RNA that binds to targets 15–25 base pairs apart in the region of interest to make a DSB (Guilinger *et al.*, 2014). It has also been shown that usage of truncated guide RNAs (17 nt) led to decreased off-target activity (Fu *et al.*, 2014). Despite these efforts, off-target activity could not be avoided. Checking for potential sites similar to the target DNA locus therefore becomes a prerequisite to prevent wastage of time and resources.

A number of computational tools have been developed and are available online for selecting a potential target within the region of interest in the genome with least or no off-target activity. *CHOPCHOP*, *CCTop*, *E-CRISP*, *Cas-OFFinder*, *GT-Scan*, *sgRNAcas9*, and *MIT CRISPR Design* are some of the popular tools among them (Xie *et al.*, 2014; O'Brien and Bailey, 2014; Heigwer *et al.*, 2014; Montague *et al.*, 2014; Labun *et al.*, 2016; Stemmer *et al.*, 2015; Bae *et al.*, 2014; Ran *et al.*, 2013b). These tools generally use similarity search methods to find off-target sites for each target and rank them. However, theoretically there is no single tool that accurately predicts all possible off-target mutations for a target site.

Another approach to improve specificity of Cas9 was engineering it through structure-guided protein engineering techniques. This method was based on studying the available crystal structure of Cas9 complexed with guide RNA and DNA and hypothesizing mutations that improve specificity. The detailed investigation of the system can be done using computational approaches. It was found from the structure that non-target strand of DNA was stabilized by a charged groove in Cas9 located in between HNH, RuvC, and PAM recognition domain. It was hypothesized that if the positively charged residues in this non-target charged groove is neutralized, it might encourage rehybridization of the DNA thereby reducing the mismatch tolerance in RNA–DNA binding. Hence mutants with individual substitutions in the 31 residues in the non-target groove were generated and their specificity was studied. Five of the 31 mutants showed decreased off-target activity by a factor of 10 compared to the wild type. After performing combinatorial mutagenesis studies using top performing mutants from previous screening, three were identified to be efficient. They were (1) SpCas9 (K855A), (2) mSpCas9 (K810A/K1003A/R1060A) or eSpCas9(1.0), and (3) SpCas9 (K848A/K1003A/R1060A) or eSpCas9(1.1). All three were assessed for specificity and their off-target activity was found to be significantly lower than that of wild type (Slaymaker *et al.*, 2016; Doudna and Charpentier, 2014; Ran *et al.*, 2013b).

Recently, researchers have started using molecular dynamics simulations to study the activity of Cas9-guide RNA complex. Conformational dynamics studies during cleavage have shown the plasticity of HNH domain and role played by non-target DNA in activation of HNH nuclease domain (Palermo *et al.*, 2016). Simulation revealed that Cas9 cleavage results in one base pair staggered end with overhangs and not blunt end in DNA (Zuo and Liu, 2016). Further studies on guide RNA-Cas9 mediated DSB mechanism may aid in designing more specific complexes without any off-target activity.

Re-engineering of Proteins to Make Their Structure More Stable

The feasibility of biological processes is initially dependent on the stability of the proteins involved. One of the main challenges faced while enhancing the stability is to not affect the activity of the target protein. Protein stability in general implies minimizing the total potential energy stored within a protein. Efficient functioning of any molecule requires it to be stable, which is generally

maintained by various interactions. In this section, we discuss various computational approaches available to analyze and predict structural changes that can be incorporated into the protein to enhance its stability.

In silico approach to enhance the stability of TEV protease

The tobacco etch virus (TEV) protein is a nuclear inclusion protease weighing 27 kDa (Allison *et al.*, 1986). The protease is involved during TEV biogenesis for the formation of single proteins after proteolytic degradation of the viral polyprotein (Adams *et al.*, 2005). Its stringent specificity and robustness make it ideal for *in vitro* protein purification and *in vivo* testing of protein–protein interactions (Wehr *et al.*, 2006). The canonical recognition sequence targeted by the protease is ENLYFQ-G/S (Adams *et al.*, 2005).

Here, *in silico* engineering of protease was carried out to enhance its stability and solubility (Cabrita *et al.*, 2007). Being a popular protein for removal of tags from recombinant proteins, its production and storage presented major challenges. The drawbacks were overcome by performing a rational search of point mutations that could be introduced in the protein for improvement of its stability and solubility than its native-state. With the aim of selecting the variants with better results, potential single-site mutations were introduced using PoPMuSiC algorithm (Kwasigroch *et al.*, 2002). The program PoPMuSiC predicts changes in the free energy of protein folding. The predicted changes were based on database-derived potentials (Gilis and Rooman, 1996). The features of TEV were improved in such a manner that (a) the structural integrity as well as the activity is sustained, and (b) the solubility remained even at higher concentrations.

The analysis of calculated potentials predicted five variants to be more stable. The calculations of potentials were obtained by linear combination of the interactions involved and the propensity of the interacting residues. Experimental characterization of the five variants was done by using assays like solubility assay, enzyme kinetics, and equilibrium unfolding analysis. Thus, the goal of designing a completely active TEV variant having better stability and more solubility was successful. Similar rational approach combining different techniques can be applied to any protein structure. Such an accomplishment becomes a powerful tool in the field of biotechnology.

Computational designing of β -sheet surfaces to boost protein stability

β -strands constitute β -sandwich or β -barrel in approximately one quarter of all known protein structures (Gerstein, 1998). In such conformations, one face of the sheet points toward the hydrophobic core of the protein, while the other face aims toward the solvent. The residues facing toward the core are vital in determining the stability of the protein by forming strong bonding interactions. However, the stability can also be detected through the solvent-facing residues. Hence, a significant amount of effort has been made to understand the structural features contributing to β -sheet stability (Lassila *et al.*, 2002; Der *et al.*, 2013; Lawrence *et al.*, 2007).

A study was conducted to redesign the β -sheet surfaces of the fibronectin type III domain of the protein tenascin (TNfn3) using the molecular modeling program Rosetta (Gerstein, 1998). TNfn3 has been a model system to extensively study protein folding and stability. Mutational changes to improve these features have already been demonstrated by many reports. The mutations stabilizing the protein structure have mostly been located in the protein core (Gilbreth *et al.*, 2014; Jacobs *et al.*, 2012).

In silico experiments conducted for this study used the all-atom energy function in Rosetta to achieve the objective. This module was parameterized with a diverse set of sequence design and structure prediction tests. In addition, an attempt was made to validate an empirical approach to achieve the protein stability. The number of salt bridges (glutamate or aspartate paired with lysine or arginine) was increased on the surface of the β -sheets. A significant challenge faced while designing β -sheet proteins was to specify the pairing. The problem was created during tertiary folding of proteins because strands that are distant in primary sequence tend to be paired in the final structure.

Interestingly, the charged residues on TNfn3 could be placed on the strands based on opposite charging through mutational studies. Also, it was ensured that β -strands that are close in primary sequence are not paired in the final protein structure. The rationale for this arrangement was that the charges would favor the folding and stability of the protein due to favorable electrostatic interactions in the folded structural state. Simultaneously, disfavoring of kinetically accessible misfolded states would occur.

Thus, dramatic increase in protein stability was achieved by optimizing interactions on the surfaces of small β -sheet proteins. Two variants of the β -sandwich protein from tenascin were obtained after designing. They were carrying seven and 14 mutations respectively on their β -sheet surfaces. Due to these changes, the thermal midpoint for unfolding was increased. Additionally, the approach based on increasing the number of potential salt bridges on the surfaces of the β -sheets was not found to be a robust strategy.

Computational Protein Engineering for Addition of Novel Function to Existing Proteins

The previous sections detailed the potential of computational protein engineering techniques in improving the specificity and stability of the target protein. Similar approaches can also be utilized to add a completely new function to a protein, such as addition of substrate binding site, metal binding site, and catalytic site. The following section describes some successful studies.

Study of adaptability of periplasmic binding proteins: Computational modification of ligand-binding site for different substrates and their application as biosensors

Biosensors are based on the general principle of detection of protein–ligand interaction and transmission of this interaction into the signal detection mechanism. Application of protein as a biosensor requires a well-defined change in conformation of its structure upon binding with ligand molecule. This change in conformation can be coupled with fluorescent detection by incorporating

fluorophores at the allosteric site of protein that can detect change induced by ligand binding (Hellinga and Marvin, 1998; Dwyer and Hellinga, 2004). Emerging protein engineering techniques allow the integration of signal transducing functional groups into the protein molecule itself that can bring electrostatic or optical changes upon interaction with ligands (Hellinga and Marvin, 1998). Moreover, specificity of protein for ligands can be altered using these techniques (Hellinga and Marvin, 1998; Reimer *et al.*, 2014).

Periplasmic binding proteins (PBPs) from *E. coli* are a widely studied superfamily of proteins for changing their ligand specificities. PBPs are periplasmic protein receptors involved in chemotaxis and nutrient uptake with wide variety of substrate specificities, including amino acids, carbohydrates, oligopeptides, metal ions, and anions (Dwyer and Hellinga, 2004). The PBPs superfamily is characterized by high sequence diversity with conserved structural domain (Hellinga and Marvin, 1998). It consists of two globular domains with ligand-binding site at the interface, connected by two- or three-stranded hinge region (Quijcho and Ledvina, 1996; Hellinga and Marvin, 1998; Dwyer and Hellinga, 2004). Ligand binding at the interface changes the conformation of protein from open ligand-free form to closed ligand-bound form by induction of large bending at the hinge region. This ligand-based conformational change of PBPs provides a great advantage in coupling it to physical detectable signal. Allosteric coupling of reporter group with ligand-induced conformational change of PBPs was successfully implemented to create allosterically regulated biosensors for trinitrotoluene (TNT), L-lactate, serotonin, and Zn(II), (Marvin and Hellinga, 2001; Looger *et al.*, 2003; Dwyer and Hellinga, 2004). Here, we have discussed a few case studies as an example for application of protein engineering in creating biosensors for TNT and metal ion Zn(II) by incorporation of metal binding site.

Modification of PBPs ligand-binding site by adding sensory function for TNT: TNT is not a natural molecule, has carcinogenic properties, and is a potent contaminant of soil and water. Development of strategies to design cost-effective sensors for detection of level of TNT in soil and water was required. Manipulation of PBPs for binding with chemical threats and pollutants like TNT might provide the advantage of designing specific cell-based detectors for these pollutants (Looger *et al.*, 2003). The ligand-binding site of three members of the PBPs superfamily of *E. coli* was engineered for binding of TNT in place of their wild-type ligand (Looger *et al.*, 2003). Three PBPs under study were arabinose-binding protein (ABP), ribose-binding protein (RBP), and histidine-binding protein (HBP). High-resolution three-dimensional structures of proteins in association with their respective ligands were obtained from databases. First, interaction studies of protein with wild-type ligands were performed to identify the amino acid residues involved in protein–ligand interactions. This step was followed by repeated combination of protein–target docking and mutation of identified amino acids residues; that resulted into 10^{45} – 10^{68} mutant structures for 12–18 amino acid residues. Resulting combinatorial mutant structures were resolved based on DEE theorem. Identification of global minimum of a semiempirical potential function was determined for system's molecular interactions. This yielded a complementary surface design for TNT in ABP, RBP, and HBP by exploring essential parameters for recognition of molecule, comprising of molecular shape, size, functional groups, chirality, charge, water solubility, internal flexibility, and molecular surface. The designed surface for TNT was electrically neutral, satisfied hydrogen bonding potential of TNT's functional groups, and hydrophobic residues of TNT were interacting with aliphatic amino acid's side chain. Interactions with aromatic side chain were also noticed in one of the design for ABP and HBP, TNT.A1, and TNT.H1, respectively.

The structures of six receptors were selected with binding specificity for TNT (with mutations ranging from 5 to 17 amino acid residues) for experimental validation. Mutant proteins were designed, overexpressed, purified, and altered by incorporation of fluorescent dye, that is thiol-reactive styryl dye conjugated to cys residue, at the site that responds to the conformation change at the hinge region upon binding of TNT. Ligand dependent changes in fluorescence were monitored for wild-type ligand, TNT, and closely related decoy structures of TNT by titration. All six receptors showed detectable binding affinity for TNT and no binding affinity with wild-type ligand was observed. Also when their binding affinity with related decoy structures was analyzed, specifically 2,4- and 2,6-dinitrotoluene (2,4-DNT and 2,6-DNT) and trinitrobenzene (TNB), it was observed that all six receptors can distinguish between TNT and their related decoy compounds with exception of ABP design, which could not recognize the absence of single methyl group in TNB. Out of the three TNT designs of RBP, affinities of two of them were comparable to the affinity of wild-type protein, that is, 0.1–1.5 mM. Affinity of TNT to nanomolar level was observed for one of the TNT designs of RBP receptor, TNT.R3, which was used for the first time to develop a biosensor for detection of underwater level of TNT into the sea using robotic vehicles for tracing underwater plumes (Mead, 2002).

Modification of Periplasmic binding proteins ligand-binding site by adding sensory function for Zn(II): Modification of maltose-binding protein (MBP) to add zinc binding site near or within maltose-binding interface will be discussed in this section (Marvin and Hellinga, 2001). DEZYMER was used to generate 20 initial designs for zinc binding site consisting of three histidine residues and one water molecule. Four of these were structurally constructed, two of them were designed to replace three maltose-binding residues (that is A1: A63_H, R66_H, W340_H; A2: A63_H, R66_H, Y155_H), and the others were located near the maltose-binding site; additional mutations were also introduced to prohibit steric clashes (this site was named as B site, B1: K42_H, E44_H, Y34_H, E45_H, R344_A; B2: P48_H, G69_H, S337_H, R66_S, Y70_A). Both A and B sites showed the same degree of fluorescence change in presence of the ligand and were able to bind the zinc molecule, while only A site could form zinc mediated formation of closed state. This suggested the need of iterative design strategy for increasing zinc binding affinity, optimization of target site, and elimination of vestigial interactions. Three strategies were used for an iterative progressive design cycle to improve binding affinity for zinc:

1. *Combination of zinc binding sites:* Out of all possible combinations of A1, A2 and B1, B2, only A2B1 combination was sterically feasible. A2B1 showed sigmoidal zinc binding; hill coefficient of 2.0 indicated cooperative interaction between two sites and upon zinc binding fluorescence level was increased by 17.7 fold. This showed that A2B1 mutant resulted in improved zinc bound closed state of protein with increased fluorescence detection signal.

2. *Primary coordination sphere optimization*: Primary coordination sphere was optimized instead of His₃Zn sites as designed in previous steps. Alanine mutagenesis screening of "A" sites was performed by mutating its each residue to alanine. H63_{II} site was common to both A1 and A2 site and its mutation to H63_{II}A partly destroyed zinc binding. Other non-overlapping residue mutations were also vital but the mutation in nearby residues, D65_{II}, demonstrates its importance in coordinating zinc ion. Molecular modeling studies were carried out that suggested the placement of forth residue at Y155_I in A1 and W340_I in A2 for optimization of coordination sphere. Mutation studies for these positions led to selection of Y155_IE and W340_IE mutants that showed higher binding affinity for zinc than their original counterparts A1 and A2, respectively. New site was designed by fusion of vertices, from His₂Glu₂ vertices of A1 and A2, to form A* site (H63_{II}, H66_{II}, E155_I, E340_I) with zinc binding affinity increased to K_d value of 5.1 μM.
3. *Exploitation of conformational equilibrium*: Overall zinc binding affinity is the sum of intrinsic affinity for closed state for zinc and intrinsic equilibrium of open and closed state in absence of zinc. Therefore, zinc binding affinity can be improved by manipulation of these factors. Two strategies were employed for manipulation of intrinsic equilibrium between open and closed state:
 - a. Vestigial maltose binding residues, E111_I and K15_{II}, single and double mutants were created by replacing them with Met and Ala, respectively in A* design. These mutants resulted in enhanced binding efficiency of zinc.
 - b. Mutations were made in protoallosteric site in hinge region that is conformationally different in two states. I329 was tightly packed in open state but binding of ligand changed its compact packing in closed state. Its mutation to I329F was studied to destabilize its open state, which led to increased zinc binding affinity for A* design, with K_d value of 350 nM.

It can be concluded from the above study that this kind of iterative progressive design approach can be utilized to convert proteins like MBP into biosensors for metal through addition of metal binding sites within the binding site of its substrate.

Computational modification of periplasmic binding proteins by addition of catalytic function for design of biologically active enzyme

PBPs structures were also tested for addition of new catalytic function, by creating catalytic site for triose phosphate isomerase (TIM) in RBP and the mutated RBP was found to be a biologically active enzyme that can support the growth of *E. coli* in gluconeogenic conditions (Dwyer *et al.*, 2004). TIM is a glycolytic pathway enzyme that interconverts dihydroxyacetone phosphate (DHAP) and glyceraldehyde 3-phosphate (GAP). This isomerization reaction requires successive transfer of two protons with enediol(ate) as intermediate and requires three catalytic residues, i.e., glutamate, histidine, and lysine. Introduction of TIM catalytic site into RBP was accomplished by mutating ligand-binding interface residues in a step-by step manner. Firstly, RBP was modified to add substrate binding site for DHAP and GAP irrespective of catalytic activity. This was accomplished using similar methods as mentioned in the case study describing addition of binding site of TNT in PBPs. Secondly, the catalytic site residues were introduced into the modified substrate binding site by specifying geometrical constraints of the active site that should be compatible with bond formation with substrates, enediol(ate) intermediate and transition state. The whole process was executed in three steps:

1. First geometrical constraints critical for interactions required for catalysis were designed.
2. Combinatorial search algorithm was employed to generate geometric constraints that satisfy constraints for both substrate specificity and catalysis simultaneously.
3. Receptor design algorithms were used to place generated complementary surface around bound substrate.

The catalytic design site obtained in this step was distinct from the designs generated for substrate binding in the first step. Fourteen (14) designs were selected for testing, out of which one design, NovoTim1.0, showed increased activity and was competitively inhibited by a known inhibitor of TIM, i.e., phosphoglycolate. NovoTim1.0 was found to be less thermostable in comparison to TIM; therefore further modification of residues surrounding binding surfaces of substrates was carried out. These modifications provided variants of NovoTim1.0, namely NovoTim1.2, which showed increased stability of protein by 15°C and increased k_{cat} (rate of reaction) and K_M (Michaelis constant) by twofold. NovoTim1.2 was formed by mutation and redesign of nine interfacial and nine binding residues of NovoTim1.0, its parent molecule. NovoTims1.0 and 1.2 were further tested by their expression in TIM deficient strains of *E. coli* for growth of bacteria on gluconeogenic substrates, glycerol and lactate, in presence and absence of inducer IPTG (isopropyl β-D-1-thiogalactopyranoside). Both versions supported growth of bacteria on lactate medium but could not utilize glycerol as a substrate for growth. Therefore, further mutants were created to design a mutant that, when transformed into bacteria, can aid bacteria to utilize glycerol as a medium for growth. NovoTims1.2.1 to 1.2.4 versions were obtained with mutations of protein surface residues and increased k_{cat} and k_{cat}/K_M values by two-fold and three-fold, respectively.

In this study, the authors clearly demonstrated how combination of computational and experimental procedures can convert non-catalytic protein into a biologically active enzyme that can aid bacteria to utilize gluconeogenic substrate for growth. This approach can be generalized to create various types of enzymes by either utilizing PBPs or any other protein.

Future Challenges of Computational Protein Engineering

With rapidly advancing computational power, *in silico* protein engineering methods have become more common and many successful applications have been reported. But some challenges still remain to be addressed in the field of computational protein engineering to have reliable and successful *in silico* protein designs. Some of the challenges are discussed here.

Initially, to lower the complexity and to decrease the computational time, the protein backbone is kept fixed and its degrees of freedom are eliminated in the protein engineering methods. Hence, residual combinations that require slight changes in backbone become unattainable. Also, these backbone methods cannot be applied to design *de novo* backbone structures. Owing to the drawbacks of fixed backbone methods, flexible backbone protein design methods like parameterization of structures, ensemble approach, and simultaneous optimization have been developed that have their own challenges. Parameterization of structures is a method that allows flexibility while modeling backbone, but decreases the degrees of freedom. Yet there are some successful studies reported using this method (Harbury *et al.*, 1995, 1998). The drawback in this method is that it does not allow explicit flexibility of backbone. In the ensemble approach, an ensemble of protein backbone structures is used to achieve flexibility and then the fixed backbone method is applied to each structure in the ensemble. The limitation in this method is that only a limited number of backbone structures can be studied. In the simultaneous optimization method, flexibility is allowed to backbone and side chains simultaneously. Although different flexibility backbone methods are established, there is an absence of good correlation between stabilities of a protein determined experimentally and computationally (Choi *et al.*, 2009). Allowing backbone flexibility thus still remains a challenge in protein engineering.

Negative design is a method to ensure specificity. Positive design involves engineering of protein to have a desired function, whereas negative design is for preventing undesired functions. In negative design, a sequence is interrogated against multiple structures so that it does not form alternate conformations. It helps in selecting sequences that form a unique structure. Prior knowledge about target structure and undesired complexes is needed in order to avoid sequences that can form undesired structures. Different negative design approaches have been reported in literature. Of these, multi-state design is a potential approach for designing proteins with specificity. Combinatorial engineering is another useful method to attain high specificity. Combining the power of computational negative design tools along with high throughput assays poses a challenge. Protein folding is a longstanding issue in protein science. Incorporating negative design to destabilize alternate structures is a challenging task (Choi *et al.*, 2009).

Another daunting task in the protein engineering pipeline is high throughput sampling of predicted structures. After computational design, all the successful designs have to be cloned in a vector, expressed in a cell, and purified for characterization. Repeating this for all successful designs one after another will be expensive, time consuming, and laborious. Hence, in future, any high throughput protein fabrication method to be developed should have automation in all the aforementioned tasks. Another approach can be constructing a gene library that represents the ensemble of proteins and expressing them simultaneously. Screening can be applied to select the protein with the desired property. So far, the selection methods applied on these libraries have been of low resolution without atomistic level sequence interrogations (Choi *et al.*, 2009).

We have discussed here some successful computational approaches that have been used to engineer proteins with better specificity, stability, and newer functionality. These examples reflect the advantages of using computational tools to mine the information embedded within the sequence and structure of native proteins, and redefine it for our interests. Though computational protein engineering methods are evolving to be imperative tools in the tedious and complex process of engineering proteins, some associated challenges still leave the scope for further innovation and improvement.

Biographical Sketch

Jaspreet Kaur received her M.Tech. in Bioinformatics from Delhi Technological University, India in 2013, and B.Tech. in Biotechnology from Amity University, India (2011). She joined the Indian Institute of Technology, Delhi, India in 2014 for her PhD program. She works in the field of computer-aided drug design and is devising computational approaches for aiding in targeted genome editing.

Vidhi Malik received her M.Tech. in Bioinformatics from Delhi Technological University, India in 2013 and B.Tech. in Biotechnology from Sardar Vallabhbhai Patel University of Agriculture and Technology, India in 2011. She joined the Indian Institute of Technology, Delhi, India in 2015 for her PhD program. Her research interest lies in next generation sequence (NGS) data analysis and computer-aided drug design.

Navaneethan Radhakrishnan received his B.Tech. in Bioinformatics from Tamil Nadu Agricultural University, India in 2016. He joined the Indian Institute of Technology Delhi, India in 2016 as Junior Research Fellow in the Department of Biochemical Engineering and Biotechnology. His research interest lies in understanding the biological systems using computational approaches.

Moolchand Sigar received his M.Sc. in Biochemistry from University of Hyderabad, India in 2011, and B.Sc. in Biotechnology from University of Bikaner, India (2008). He joined Indian Institute of Technology, Delhi, India in 2012 for his PhD program. His research interest lies in engineering and production of therapeutic proteins.

Anjani Kumari received her B.Tech. in Biotechnology from Amity University, India in 2015. She completed her M.S. (Research) program in Biochemical Engineering and Biotechnology at IIT Delhi in 2017. Her research interest lies in computer-aided drug discovery.

Durai Sundar is a DuPont Young Professor in the Department of Biochemical Engineering and Biotechnology at Indian Institute of Technology, Delhi. He obtained his education from Pondicherry University and Johns Hopkins University, Baltimore, USA. He is a specialist in molecular and computational biology and his current research interests are in rational design of genome editing tools and in the biological activity of natural drugs.

Protein Design

Ragothaman M Yennamalli, Jaypee University of Information Technology, Wanknaghat, Himachal Pradesh, India

Introduction

A cursory search of the Protein Data Bank (PDB) with the keyword “*de novo*” returns 962 entries, while for the keyword “designed”, 6225 entries were returned [as of August 2017]. Although these numbers (*de novo* or designed structures) are 1000 times lesser in magnitude (compared to the total number of structures the PDB holds, which is close to 135,000 structures), these ~7000 structures indicate how far the field of protein design has advanced, since 1950s. Protein designing projects are ambitious in their goal due to the simple yet complex problem of protein folding. Much has been learned about how a protein folds, and these fundamental knowledge have helped further the area of protein design to conceive proteins with imaginative structures (Richardson and Richardson, 1989; Bowie *et al.*, 1991).

The impetus for protein design is two-fold: (i) assumption that we can design a complex natural system from first principles, and (ii) the “made to order” macromolecules that can solve important biochemical hurdles. The basic or fundamental problem with protein design in achieving a three dimensional, stable, and functional macromolecule is to cross the conformational entropy from the primary to the tertiary structure (Bowie *et al.*, 1991; Dahiyat and Mayo, 1997). There are many methods that can be used to reduce the conformational entropy (Baxa *et al.*, 2014). These include covalent cross-links and other artificial constraints that limit the conformational possibilities of the designed molecule (Leitner *et al.*, 2010; Sinz *et al.*, 2015).

There have been two basic design principles employed in designing proteins *de novo*: positive design and negative design (DeGrado *et al.*, 1989). Positive design of protein structures is the idea to design a protein with the desired structure as the goal, and rationally add/remove residues to achieve that structure. In contrast, negative design involves designing a structure along with ways to reduce formation of or competition from alternative conformations that may arise. While both methods involve rational design, there are advantages of using one over the other. Nevertheless, *de novo* design of protein structures using both methods has been successful to a varying degree. Fig. 1 shows a representative set of structures that have been successfully designed and have advanced the field of protein design.

Since 1950s, designing alpha helices took precedence than the beta sheets, due to:

- The stabilizing hydrogen bond network (Fig. 2).
- The observation of isolated helices being stable in solution (Brown and Klee, 1971; Kim and Baldwin, 1984; Marqusee and Baldwin, 1987; Shoemaker *et al.*, 1987; Marqusee *et al.*, 1989).
- Its oligomerization property observed by Crick, Pauling and Corey in supercoiled helices that when two helices twist around each other there are 3.5 residues per turn, which is less than the ideal 3.6 residues per turn rule, thereby leading to a repetition of the entire structure at every seven residues (Crick, 1953; Pauling and Corey, 1953).
- The possibility of designing the minimal sequence, which can be repeated to construct a four- or six-bundle helices that can either self assemble or assemble in the presence of an external assembly inducer (Schafmeister *et al.*, 1997).

Fig. 1 A representative set of structures that have been designed *de novo*, where they are shown in cartoon representation with helices colored cyan, β -strands colored red, and loops colored magenta. (A) Octameric *de novo* Designed Peptide (pdb id:1l4x), (B) *de novo* Design of an Antibody Combining Site (pdb id:1ivl), (C) Self-Assembling Cyclic Protein Homo-Oligomer (pdb id:4hb5), (D) Right-Handed Coiled Coil Tetramer (pdb id:1rh4), (E) Beta Beta Alpha Protein Motif (pdb id:1fsv), (F) *de novo* Design of a Hyperstable Non-Natural Protein-Ligand Complex (pdb id:5tgw), (G) Giant Double-Walled Peptide Nanotube (pdb id:5vf1), (H) *de novo* Designed Mini Protein Hhh_Rd1_0142 (pdb id:5uoi), (I) Computationally Designed Left-Handed Alpha/Alpha Toroid With 12 Repeats (pdb id:5byo), and (J) Computationally Designed Vitamin-D3 Binder (pdb id:5iep).

Fig. 2 Helix stabilizing properties. Schematic representation of an ideal helix indicating the various properties that stabilize the helix. Adapted from Bryson, J.W., *et al.*, 1995. Protein design: A hierarchic approach. Science (New York, NY) 270 (5238), 935–941.

Fundamentals

Before taking a sequence and designing it into a novel structure (α -helical or β -sheets or mixed), few pointers need to be kept in mind:

1. Similar stretch of residues can form different secondary structure.
It has been observed that the same residue stretch of up to five amino acids can form different conformations, such as α -helix, β -strand, and loop. This indicates that a sequence forming a structure is dependent on its local environment.
2. There are only so many folds present.
The relatively limited number of folds in the protein universe can be considered as a double edged sword. The 1000 odd folds we know today indicate that proteins tend to fold in one of the restricted ways. It also suggests the possibility of creating new folds using computational tools. The former has led to the reverse folding problem, called threading, where a sequence is checked for its compatibility to fold into one of the known folds.
3. Reducing the entropy of protein by introducing disulfide bonds (Wetzel, 1987).
4. Glycine introduces relatively more conformational freedom than the other 19 amino acids.
5. In contrast, Proline introduces less conformational freedom due to its covalent bond with the main chain.
6. It is known that the residues at the end of a helix are positively (at the C-terminus) and negatively (at the N-terminus) charged, which help in stabilizing the helix by balancing the helix dipole charge. Thus, changing the helix stabilizing residues influences the stability of a protein (Nicholson *et al.*, 1988; Richardson and Richardson, 1988).
7. If a core of a protein has a cavity, filling the cavity makes the protein destabilize it.

Designing an α -Helical Structure

Historically, alpha helical peptides and all- α proteins were relatively easier to design. In order to design alpha helical proteins, the sequence under consideration should be scrutinized with the following guidelines.

1. The sequence should be able to form amphiphilic secondary structures, where there is a periodicity of polar and nonpolar residues. For example, every third or fourth position being nonpolar.
2. A general rule of thumb is that the sequence should have residues that are highly likely to be part of a helix (Ala, Glu, Leu, and Met) (Richardson, 1981). Specifically, multiple alanine residues stabilize the helix. However, if the nonpolar periodicity of 3 or 4 is not maintained, then there is a lower preference to form a helical structure (Xiong *et al.*, 1995).
3. Introduction of salt-bridges and hydrogen bonds between side chains of residues that are one helical turn away (Marqusee *et al.*, 1989; Lyu *et al.*, 1990; Huyghues-Despointes *et al.*, 1993; Park *et al.*, 1993; Scholtz *et al.*, 1993).
4. A charged residue can be introduced at the N or C terminus of the α -helix, creating a macrodipole (Fig. 2).
5. Capping the helix ends with Asn, Ser, Asp, or Thr to satisfy the hydrogen-bond donors and acceptors.
6. Adding hydrogen bond(s) between side chains of residues that are one helical turn away.
7. In the case of Ser, Thr, and other amino acids that can be phosphorylated, their location in the interior of the helix may lead to destabilization. However, the N-terminus capping of a phosphorylated residue leads to stabilization of the helix. This is due to the electronic interaction of the phosphorylated residue with the peptide backbone.

Certain tools that can be used specifically to design helices are helical wheel and predicting helicity.

Helical wheel is a simple tool to identify if the distribution of charged residues and hydrophobic residues would lead to aggregation. When the helix has majorly hydrophobic or nonpolar residues on one side, there is a high chance of protein aggregation. This highly efficient tool has been used for designing proteins that are primarily coiled coil, and for helix bundles comprised of 3, 4, 5, and 6 helices. Specifically, the tool becomes effective when these helices are linked by loops or turns and to check if the “ridges in groove” or “knobs in holes” packing needs to be checked.

Some of the tools that plot a helical wheel for a given sequence are: DrawCoil 1.0 (see Relevant Websites Section), Pepwheel (see Relevant Websites Section), and Helical Wheel Projection (see Relevant Websites Section).

Also, the designed sequence can be checked for its propensity to form helices by submitting the sequence to AGADIR (see Relevant Websites Section) that calculates helicity (Munoz and Serrano, 1994, 1995a,b, 1997; Lacroix *et al.*, 1998).

Designing a β -Sheet Structure

β -sheets can be parallel, antiparallel, and mixed in nature. Due to absence of planarity, parallel β -sheets are less stable than antiparallel sheets. This is due to the relative absence of inter-strand hydrogen bonds in parallel β -sheets, which provide for stronger interaction. Fig. 1(B), (G), and (J) highlight the successful design of a β -strand rich proteins.

In 1996, the design of a decapeptide adopting a β -hairpin structure involving a β -bulge and three other dodecapeptides adopting a type I' β -turn made the protein design possible for β -rich proteins (de Alba *et al.*, 1996; Ramirez-Alvarado *et al.*, 1996; Stanger and Gellman, 1998). These reports fueled enthusiasm in four different groups to design a three stranded antiparallel β -sheet proteins (each differing in residue length) (Kortemme *et al.*, 1998; Schenck and Gellman, 1998; Sharman and Searle, 1998; de Alba *et al.*, 1999). Irrespective of the method they employed, some of the criteria that were included in all the above mentioned β -sheet proteins are:

1. Residues that have higher β -strand propensities were included in the sequence.
2. Inter-strand pairs were selected that have higher preference to make a stable bond.
3. Involving positively charged residues (2 to 5 residues, at least) so that aggregation of proteins is eliminated, and increases solubility.

Positive charge distribution is essential in designing β -sheet proteins, because when they are distributed on both sides of the sheet, aggregation of proteins is reduced to a large extent. Another method to design a β -sheet protein with a stable hydrophobic core involves adding a type I' β -turn to the designed β -hairpin protein by using residues, such as Phe, Trp, Asn, and Gly, so that the side chains face the other strand's hydrophobic residues' side chains (Tyr and Val) (Griffiths-Jones and Searle, 2000).

Similar to α -helices, some of the guidelines to be used while designing β -sheet proteins are as follows:

1. The role of a β -turn is crucial, as it dictates the β -strand. This is a necessary but not a sufficient condition while designing β -sheet proteins. For example, the D form of Pro in the turn stabilizes the β -hairpin structure, compared to the L form.
2. Residues that have high propensity to form β -sheet should be used. For example, Val, Ile, Phe, Trp, Tyr, Leu, and Thr.
3. Gly should be avoided, as its incorporation leads to destabilization.
4. Including salt-bridge forming residues in inter-strands stabilize the β -sheet protein. For example, a salt-bridge formed between Glu and Lys residues. On the same note, salt-bridges at the ends of β -hairpin are more stabilizing.
5. Presence of interactions between hydrophobic residues, such as Ile-Trp, Ser-Thr, and Trp/Val-Tyr/Phe stabilize the protein as their contributions are larger.
6. Side chain-side chain interactions from diagonal directions between two strands also contribute towards stability. For example, Tyr-Lys, Phe/Trp-Lys/Arg interactions.
7. Presence of a right-handed β -sheet twist.
8. The hydrophobic cluster between the strands contributed by Trp, Val, Phe, and Tyr residues vastly stabilize the β -sheet proteins.
9. As a general rule of thumb, incorporating disulfide bonds stabilize the protein with β -hairpin structures.

Relatively speaking, there are fewer examples of β -sheet proteins designed *de novo*. However, α/β mixed structures have been designed with great success (Struthers *et al.*, 1996). For example, Top7 by David Baker group and a $\beta\beta\alpha$ motif structure that is similar to a zinc-finger, which has a β -hairpin structure (Kuhlman *et al.*, 2003).

Tools Currently Available for Protein *de novo* Design

Irrespective of topology of the intended protein to be designed, some tools are listed below that are routinely used for *de novo* protein design, and also keeping in mind the ease of use from user's perspective.

Rosetta and Rosetta Design

Among the tools that are currently available, Rosetta ([Simons *et al.*, 1999](#)), developed by David Baker group at University of Washington, has been the most popular and widely used ([Jiang *et al.*, 2008](#); [Siegel *et al.*, 2010](#); [Damborsky and Brezovsky, 2014](#)). The suite of software (see Relevant Websites Section) has sped the design of protein structures. Details of Rosetta's design algorithm and specifics are discussed in [Simons *et al.* \(1997, 1999\)](#), [Raveh *et al.* \(2010\)](#) and [DiMaio *et al.*, \(2011\)](#) and they have been reviewed elsewhere ([Mandell and Kortemme, 2009](#); [Der and Kuhlman, 2011](#)). Specifically, Rosetta Design (see Relevant Websites Section) can be accessed via the command line interface of Rosetta or via webserver ([Lyskov *et al.*, 2013](#)).

Evodesign

Evodesign (see Relevant Websites Section) developed by Zhang group at University of Michigan is a web based server to design protein sequences using a scaffold as an input. The scaffold is searched against the known protein families and the resulting conformation takes into consideration local environmental factors, such as solvent accessibility, packing, and secondary structure ([Mitra *et al.*, 2013](#)).

Protein WISDOM

Protein Wisdom (see Relevant Websites Section) is a web server tool for designing proteins from sequence information. The design and validation involves two steps: using either a rigid or flexible scaffold (or template), a sequence is selected from a pool of candidate sequences; and validation is done by fitting the sequence into known folds to calculate the "fold specificity" ([Smadbeck *et al.*, 2013](#)).

OSPREDY

Open Source Protein REdesign for You (OSPREDY) (see Relevant Websites Section) like Rosetta is a suite of programs developed by Donald group at Duke University. While Rosetta is licensed free for academics, OSPREDY is open-source and freely available to download and use. OSPREDY uses protein flexibility to create low-energy corpus of structures to identify the globally optimal structure. From the user's perspective, OSPREDY runs as a standalone tool and is not available as a web-server ([Gainza *et al.*, 2013](#)).

ISAMBARD

Intelligent System for Analysis, Model Building And Rational Design (ISAMBARD) (see Relevant Websites Section) is another open-source suite of software for designing proteins developed by Woflsoon group at University of Bristol. Keeping with the popularity of Python, ISAMBARD uses predefined python object based method to design protein structures. Those with a basic python skill will be able to use this modular and scalable software to design protein structures ([Wood *et al.*, 2017](#)).

FireProt

Rather than a general protein design tool, FireProt (see Relevant Websites Section) is a specific protein design tool for designing multiple-point mutant proteins that are likely to be thermostable ([Musil *et al.*, 2017](#)).

iRDP

Similar to FireProt, in-silico Rational Design of Proteins (iRDP) (see Relevant Websites Section) is a webserver that uses a four-step approach to rationally design proteins. Specifically, from the input it compares existing protein structures for structural stability factors, followed by mutational analysis, and their impact to local environmental changes, and identifying the optimal structure that would have a higher thermostability than the previous structure ([Panigrahi *et al.*, 2015](#)).

IPRO

Iterative Protein Redesign and Optimization procedure (IPRO) (see Relevant Websites Section) from the Maranas group at Pennsylvania State University, uses a combinatorial approach to redesign a protein library using energy based scoring functions. As claimed by the developers, it uses an iterative process to make additive mutations that improve the designed protein's substrate specificity ([Saraf *et al.*, 2006](#); [Fazelinia *et al.*, 2007](#)).

Scaffold Selection

Keeping in view that new protein can be designed from pre-existing structures; ScaffoldSelection (see Relevant Websites Section) is a tool that scans large sets of structures for a particular reaction scaffold (Malisi *et al.*, 2009). For the user, the tool can be downloaded as binaries for Linux, Mac, and Windows operating systems and run as a standalone software/tool.

Pocketoptimizer

Pocketoptimizer (see Relevant Websites Section) is an allied tool that can be used to design active site region, either to improve or modify ligand/substrate binding (Stiel *et al.*, 2016).

Conclusions

Protein design is an active, exciting area of research that has wide applications in drug design, medicine, and advancing the study of protein folding. When designing protein structures, one has to ask few questions and these questions drive or direct the use of tools to answer those questions.

1. Is the aim to engineer a protein's function/activity or designing a structure *de novo*?
2. Is the design fitting with the already known do's and don't's?
3. Is there another variable that is specific for the protein and its intended use?

There can be more additional questions added and the framework/checklist can act as a guide to the specific task in hand.

While, there are many success stories in *de novo* protein design, there are some challenges for the road ahead. Some of the challenges that have been discussed (Kuhlman *et al.*, 2009) are:

1. Sampling the conformational space of the backbone to move towards a completely flexible backbone based design. Currently, majority of the *de novo* designed proteins are on the basis of having a rigid scaffold or frame throughout the design pipeline.
2. To reduce the presence of alternate conformations from the desired/designed conformation.
3. Designing specific protein-protein interactions using a much easier and faster method.

Recently, Rocklin *et al.* from David baker's lab have used minimal proteins (proteins having a residue length below 50 amino acids) to understand the factors that determine protein folding. Specifically, they used computationally driven approach, where four topologies ($\alpha\alpha\alpha$, $\beta\alpha\beta\beta$, $\alpha\beta\beta\alpha$, and $\beta\beta\alpha\beta\beta$) were designed using 5000–40,000 sequences for each topology. Using yeast based proteolysis assay, a stability score was given to each designed protein, which enabled them to identify 2788 stable proteins. Such "massively-parallel" design has indeed pushed the limits of high-throughput design and the method can be applied to proteins of more than 50 amino acids in length (Rocklin *et al.*, 2017).

Biographical Sketch

Ragothaman Yennamalli is an Assistant Professor at Jaypee University of Information Technology, Wagnaghat, Himachal Pradesh, India. He completed his PhD in Computational Biology and Bioinformatics from Jawaharlal Nehru University, New Delhi. He conducted postdoctoral research at Jawaharlal Nehru University in India and at Iowa State University (2009–2011), University of Wisconsin-Madison (2011–2012), and Rice University (2012–2014) in USA. He is a structural and computational biologist with more than a decade of experience in predictive modelling and biomolecular simulation projects. Dr. Yennamalli's skills involve molecular docking, molecular dynamics simulation, coarse grained modelling, machine learning, data mining, data analytics, and molecular modelling. Background

The need for reduction of cost and time had led to the emergence of computer-aided drug design technology in drug discovery pipeline. While molecular docking and other high throughput virtual screening have played significant roles in screening large libraries of compounds, atomistic Molecular Dynamics (MD) simulation, is increasingly gaining trust in guiding the prediction of comprehensive drug-target binding interactions with the cognate protein receptors, which are important in successful hit discovery and optimisation. The classical 'lock-and-key' theory of ligand binding where the lock is a rigid protein receptor complemented by small molecules which act as keys, is no longer able to account for the drug binding event, as conformational changes upon ligand binding to receptor proteins are well known. These conformational changes range from modest loop motion to hinge bending (Jorgensen, 1991). Most docking programmes can only give a static picture ('lock-and-key') of what is happening during drug binding. Thus, MD simulations are the method of choice, to study drug-target binding allowing conformational changes to be investigated further (De Vivo *et al.*, 2016).

In a typical all-atom MD simulation, the movements of all the atoms of a drug and its target protein (or other macromolecule) in physiological solvent environment are simulated over time (lasting for hundreds of nanoseconds or longer) in a series of discrete short time steps (e.g., 2 fs). At each time step, the forces on each atom are computed (based on force field method) from the atomic position and velocity according to Newton's Laws of Motions. The trajectories obtained will be used to study the dynamics and behaviours of the system as well as making prediction on the binding affinity of the ligands to the receptor. The use of molecular dynamics (MD) simulation along with the current advancement in computational technology allows such valuable prediction to be obtained with reasonable cost and time. The applications of MD simulation in drug discovery is wide ranging, from the investigation of protein-ligand binding and unbinding to mutation effects for this binding and computing the free energy of binding. The application of molecular dynamics in relation to drug discovery in general have been reviewed previously (De Vivo *et al.*, 2016; Durrant and McCammon, 2011; Borhani and Shaw, 2012). In this review, we focus specifically on the contribution of MD simulations in the attempt to battle tuberculosis (TB), one of the ancient deadly diseases that still persist today.

Mycobacterium tuberculosis (MTB), the causative agent of human tuberculosis (TB), is a bacterial pathogen, listed as one of the top ten causes of death worldwide. Currently, it is the leading cause of death from a single infectious agent surpassing even human immunodeficiency virus (HIV) with 1.4 million people killed per year and an estimated 2 billion people are latently infected worldwide. In 2016, an estimated 10.4 million people developed active TB (WHO, 2017). MTB (Fig. 1) has been known to infect human from thousands of years. In general, there are two phases in MTB life cycle, i.e., the replication phase (active TB) and the dormant phase (inactive TB) (Fig. 2). Both phases involve different metabolic pathways, with carbohydrate as the main source in active TB phase, and lipid as sole carbon source in dormant phase. To date, most drugs available for MTB infection are only targeting the replication phase of the MTB infection. However, there is an imminent need for finding effective drugs that can target MTB in the dormant phase, as 95% of current MTB infection is becoming latent.

MTB has a remarkable ability to avoid the attacks of host's immune system and has developed sophisticated strategies for successful infection that make it challenging to treat the disease. The current MTB therapy is a two-month intensive phase of a four-drug combinations of isoniazid (INH), rifampicin (RIF), pyrazinamide (PZA) and ethambutol (EMB) followed by a longer continuation phase of INH and RIF to eradicate the remaining bacilli that have entered a dormant, slowly-replicating latent phase.

Fig. 1 Scanning electron microscope (SEM) image of H37Rv strain (ATCC 25618) of *Mycobacterium tuberculosis*.

Fig. 2 Stages of transmission and progression of MTB infections. Two different metabolic pathways used by MTB in replication and dormant phase of MTB infection are shown.

Fig. 3 shows the targets of these drugs in MTB. The emergence of multidrug-resistant MDR-TB strains (resistance to RIF and INH) complicates the therapy as the treatment can extend up to 2 years and requires more toxic, less efficacious second- or third-line agents such as fluoroquinolone and kanamycin. The appearance of the extensively drug-resistant tuberculosis (XDR-TB) and totally drug-resistant tuberculosis (TDR-TB) have made the treatment even more difficult (Hoagland *et al.*, 2016) and expensive. The average cost of treating a TB patient increases with resistance; from \$18,000 to treat drug-susceptible TB to \$513,000 to treat the most drug-resistant form of the disease (XDR TB). The therapy takes a long time to complete, disrupts lives, and has potentially serious and side effects such as depression or psychosis, hearing loss, hepatitis, and kidney impairment (CDC, 2017).

Fig. 3 The targets of the existing antitubercular drugs and the newly discovered targets of MTB.

Understanding the basic biology of the pathogen that underlie the development and spread of MDR TB is as equally important as developing novel effective antitubercular for drug-susceptible and drug-resistant TB in the battle with this disease. In the former case, one really needs to look at the resistance mechanism at the molecular level as it not only improves our understanding of the pathogenesis of MTB but hopefully to prevent the development of drug resistance in the future. Similarly, in order to develop novel antitubercular, one also requires deep understanding of drug-target interactions such that the agent will be more active and selective.

The main challenges faced towards developing anti-TB drug include the organism's slow replication, the ability of *M. tuberculosis* to survive in a dormant state and its capability to develop resistance against drugs, especially towards isoniazid (INH), the first line drug for the treatment of TB. INH is a prodrug, catalysed by a catalase peroxidase enzyme (KatG), that produces the ultimate inhibitor for enoyl-acyl carrier protein reductase (InhA). InhA is involved in the synthesis of mycolic acid components of the outer mycobacterial cell (Telenti *et al.*, 1997; Wang *et al.*, 1998; Fang *et al.*, 1999; Vilcheze *et al.*, 2000). Mutation(s) in *katG* (Banerjee *et al.*, 1994) has been associated with high level of INH resistance. Besides *katG*, mutations in other MTB genes, such as *inhA*, *ahpC*, *kasA* and *ndh* are also involved in the INH resistance (Vilcheze *et al.*, 2000; Piatek *et al.*, 2000; Slayden and Barry, 2000; Torres *et al.*, 2000) with the mutations within *inhA* have been reported up to 32% in INH-resistant isolates (Heym *et al.*, 1995; Morris *et al.*, 1995; Lee *et al.*, 1999; Kiepiela *et al.*, 2000). Beside INH, MTB has been shown to develop resistance towards other TB drugs. Table 1 lists some examples of current tuberculosis drugs and their targets as well as genes associated with their resistance (Telenti, 1998; Zhang *et al.*, 2006; Hards *et al.*, 2015; Lewis and Sloan, 2015).

To date, in the quest for developing new active antitubercular, there have been many new drug targets identified alongside the well established targets for MTB and these numbers are increasing as new technologies emerged. Recent reviews (Wellington and Hung, 2018; Ferraris *et al.*, 2018; Hoagland *et al.*, 2016) have provided interesting snapshots of some of these molecular targets which are involved in vital cellular biological processes such as cell wall synthesis, energy metabolism, protein synthesis, phosphate transport and the metabolism of key molecules and cofactors. Here, we aim to provide dynamic snapshots of these molecular targets using MD simulations to further improve our understanding of the action and resistance mechanisms of various

Table 1 Current tuberculosis drugs, their molecular targets and gene(s) associated with their resistance

Drug	Mechanism of action	Target	Gene(s) involved in resistance
Isoniazid	Inhibition of cell wall mycolic acid synthesis	Enoyl acyl carrier protein reductase (InhA)	katG, inhA,
Rifampicin	Inhibition of RNA synthesis	RNA polymerase, subunit B (rpoB)	rpoB
Pyrazinamide	Depletion of membrane energy	Membrane energy metabolism, precise target still debatable	pncA, panD, rpsA
Ethambutol	Inhibition of cell wall synthesis	Arabisoyl transferase	embCAB
Streptomycin	Inhibition of protein synthesis	Ribosomal S12 protein and 16SrRNA	rpsL, rrs
Kanamycin	Inhibition of protein synthesis	16SrRNA	Rrs
Capreomycin	Inhibition of protein synthesis	16SrRNA, 50Sribosome, rRNA methyltransferase (TlyA)	Rrs, tlyA
Fluoroquinolones	Inhibition of DNA synthesis	DNA gyrase	gyrA, gyrB
Ethionamide	Inhibition of mycolic acid synthesis	Acyl carrier protein reductase (InhA)	inhA, etaA/ethA
Para-amino salicylic acid	Inhibition of folate pathway	Dihydrofolate reductase, dhfrA	thyA, dhfrA
Bedaquiline	Inhibition of ATP synthase	The proton pump of mycobacterial ATP (adenosine 5'-triphosphate) synthase	atpE
Delamanid	Inhibition of mycobacterial cell wall components, methoxy mycolic acid and ketomycolic acid synthesis	Deazaflavin dependent nitroreductase	fgd, Rv3547, fbiA, fbiB, and fbiC

drugs towards their corresponding TB targets and how the results have been instrumental in the optimisation stage of drug discovery against existing and newly discovered targets.

Applications and Case Studies

MD simulations have been applied to investigate the structural dynamics of various drug targets and to unravel mechanistic information. Such information includes the effects of mutations, role of waters on the ligand binding as well as the prediction of potentially new ligand binding site. The methodology has also been used in *in silico* drug discovery campaign, from preparation of protein structure for structure-based drug design and discovery studies, to evaluation of the binding interactions, stability and free binding energies of protein-ligand complexes (Fig. 4). These applications in battling tuberculosis are discussed in greater detail below.

Elucidating the Structural Dynamics and Mechanisms of MTB Targets

The static models provided by docking simulations give valuable insights into macromolecular structure, but drug binding is a dynamic event. At physiological condition, macromolecules (targets) are in constant motion surrounded by solvents. Drug binding to the target typically results in the target's conformational shifts that is usually different in the absence of drug binding. This binding event, is governed by enthalpic contribution which stabilizes the interactions through the formation of hydrogen bonds, salt bridges and/or van der Waals interactions; as well as the entropic penalties from the loss of conformational freedom of the target and drug. Amino acid mutations occurring in many MTB drug targets, which have contributed to many clinically drug-resistant strains, may disrupt shape complementarity as well as physicochemical compatibility that affect the binding of drug to the target (Lahti *et al.*, 2012). All these dynamic events, can easily be studied using MD simulations.

The understanding of conformational changes of selected MTB targets is crucial in designing effective molecules for drug discovery. For this reason, *in silico* site-directed mutagenesis has been performed to understand how the functionally important binding site residues in targeted MTB enzymes affect the conformational changes as well as the binding of potential inhibitors. To illustrate, studies on an enzyme involved in glyoxylate pathway is chosen as an example. As dormant phase MTB is in non-replicating mode, MTB shifts its metabolism pathway to utilise fatty acids or lipids as the carbon source to survive in the macrophage. Therefore, the energy of MTB is produced via glyoxylate pathway to bypass the oxygen-dependent tricarboxylic acid cycle (also known as Krebs cycle). Shukla and co-workers revealed that H46A, L418A and F345A mutations in isocitrate lyase, an enzyme in the glyoxylate shunt, resulted in the loss of activity due to geometry alteration in the binding site. The altered active site geometry disturbed the enzyme transition state, rendering the enzyme inactive (Shukla *et al.*, 2018, 2017a,b; Fig. 5). A similar approach has also been used against different MTB targets such as pantothenate synthase (Pandey *et al.*, 2018), catalase peroxidase (Singh *et al.*, 2018; Srivastava *et al.*, 2017; Pimentel *et al.*, 2017; Unissa *et al.*, 2017), pyrazinamidase (Aggarwal *et al.*, 2018), RecA Mtu Intein (Zwarycz *et al.*, 2017), RNA polymerase (Singh *et al.*, 2017), RpoB protein (Nusrath Unissa *et al.*, 2016), where conformational stability as well as shrinking or enlarging the binding site cavity caused by mutations were studied with respect to their effect on individual functionality of MTB drug targets.

Fig. 4 General applications of MD simulations in (A) basic research and (B) *in silico* structure-based drug design and discovery.

Apart from studying the conformational changes upon mutation, MD has also been used to understand the functional behaviour of drug target in its different subunit form. To illustrate, Parker and co-workers revealed that disruption of the tetrameric conformation of 3-deoxy-D-arabino-heptulosonate 7-phosphate synthase (DAH7PS) by substitution of G232P to dimer resulted in changes in conformation as well as the polar and solvation properties by MD analysis. This ultimately resulted in the reduction of catalytic efficiency and the loss of allosteric response, suggesting the importance of maintaining

Fig. 5 (A) ICL In its tetrameric form (PDB ID: 1F8I). (B) Point mutations H46A, H180A, F345A and L108A constructed by Shukla *et al.* (2015, 2017a,b, 2018). L108 and H46 are distant from the ICL binding site (in surface representation).

the quaternary structure (i.e., the tetrameric form) for its function. This was further validated experimentally with enzyme kinetics study (Jiao *et al.*, 2017).

2-*trans*-enoyl-ACP (CoA) reductase (InhA) is involved in the biosynthesis of mycolic acid, an essential unique component of the MTB cell wall. This enzyme is the primary target of isoniazid (the first-line antituberculosis drug). Therefore, inhibition of InhA by isoniazid will hinder the synthesis of the MTB cell wall. MD simulations have also been used by Basso's group to investigate the crowding effect on 2-*trans*-enoyl-ACP (CoA) reductase (InhA) enzyme from MTB (Rotta *et al.*, 2017). As crowding effect is impossible to mimic in *in vitro* experiment, investigation of the crowding effect on the respective protein was performed *in silico*, by mimicking the cellular crowd (Ferreira *et al.*, 2016). Briefly, the behaviour of InhA in different solutions such as sucrose, glucose and PEG at different concentration is compared. Their study suggested that the flexibility of InhA and the variation in the volume of the active site is strongly related to the concentrations of the sucrose and glucose solutions used, with high rigidity and compactness of InhA shown on the B-factor interpretation in highly concentrated sucrose and glucose solutions mimicking the cellular environment. Based on these observations, Basso and co-workers suggested that the active site packing of InhA could interfere with processes such as substrate entrance and/or product release. The findings from this study also serve as a surrogate of *in vivo* intracellular medium for anti-tuberculosis drug screening campaigns (Rotta *et al.*, 2017).

In combination with QM/MM (hybrid quantum mechanics/molecular mechanics), MD simulation is also able to provide in-depth details of a chemical reaction. Yao *et al.* (2017) utilised QM/MM approach to study the catalytic mechanism and the nature of the rate-limiting step involving the shikimate kinase enzyme in the shikimate pathway which has recently been recognised as an antimicrobial drug target for MTB. The shikimate kinase pathway is used by plants and bacteria to synthesize shikimate, which is a common precursor in the synthesis of aromatic amino acids and secondary metabolites. Their results were found to correlate well with the experimental data where the phosphorylation transfer process, which is the rate-limiting step of SK-catalysed phosphorylation of shikimic acid (SKM), is a concerted one step reaction proceeding through a loose transition state.

Prediction of a New Ligand-Binding Site in MTB Targets

Predicting a new ligand binding sites on receptor structures, which are obtained either from experimental or computational methods, is a useful first step in structure-based drug design (Jian *et al.*, 2016). MD simulations have also been used to predict the binding site of isoniazid (INH) in MTB's KatG protein, in which its S315T mutation has been associated with INH resistance, presumably due to its reduced affinity (Yu *et al.*, 2003). INH is a prodrug which needs activation by the KatG protein to exert its action. Although the exact binding site of INH to KatG is unknown, it has been previously proposed that there are three potential binding sites of INH on KatG, close to the heme site, referred to as Site-1, Site-2 and Site-3 (Kamachi *et al.*, 2015a,b; Vidossich *et al.*, 2014). To pinpoint the exact binding site, a 100 ns MD simulations for each of the docked complex of INH at the three potential binding sites of the wild-type and S315T mutant KatG were carried out (Srivastava *et al.*, 2017). Interestingly, only Site-1 bound INH resulted in conformational change to the important heme group of KatG, suggesting that Site-1 is the main INH binding site. Moreover, further MD trajectories analysis revealed no significant change to RMSD, RMSF, Rg, hydrogen bond occupancy and solvent-accessible surface area (SASA) for both wild-type and mutant systems of all but Site-1 bound INH systems. In addition, subsequent estimation of INH binding energy with MM-PBSA from the stable MD trajectories of the complex revealed a strong binding energy for Site-1 bound INH (wild-type) with a value of

– 44.201 kJ/mol versus – 0.090 kJ/mol and – 3.805 kJ/mol in Site-2 and Site-3, respectively. A comparatively weaker binding affinity of INH in Site-1 of the mutant S315T (– 35.307 kJ/mol), with reduced hydrogen bond occupancy involving key residues for INH activation, i.e., Tyr229, His108 and Arg104, further establishing Site-1 as the main INH binding site.

MD simulations have also been used to assist prediction of potential allosteric sites of various MTB targets, such as the UDP-Galactopyranose Mutase (UGM) (Shi *et al.*, 2016) and the shikimate kinase (SK) enzymes (Mehra *et al.*, 2016a). UGM plays an important role in the biosynthesis of mycobacterial cell wall, as it catalyses the reversible conversion of UDP-galactopyranose (UDP-Galp) to UDP-galactofuranose (UDP-Galf), which is required for the building of arabinogalactan chain in the mycobacterial cell wall (Besra *et al.*, 1995; Nassau *et al.*, 1996). UGM gene knockout was found to inhibit the growth of MTB, indicating that UGM is essential for the growth of mycobacteria (Pan *et al.*, 2001). Moreover, both UGM and Galf are not found in human, suggesting that UGM is a viable anti-TB drug target. Recently, Pinto and colleagues (Shi *et al.*, 2016) have successfully discovered a second druggable binding site in UGM based on the analysis of 80 ns MD simulations (RMSF, number of contacts and interaction energies) of the complex of a novel non-substrate-like UGM inhibitor (MS-208, identified from saturation transfer difference (STD) NMR experiments and kinetic assays), docked at the allosteric site (A-site, predicted from blind docking) or the active site (S-site) of the UGM enzyme. As the docked complex (at the A-site) was found to have much smaller fluctuations, larger number of contacts, and larger interaction energy than the complex of inhibitor docked at the S-site, the authors concluded that MS-208 is likely to bind to the A-site. Further point mutation of the two interacting residues on the two flanking loops of A-site (Y253A and D322A) resulted in a significant loss in MS-208 inhibitory activities, thus further supported this conclusion.

In a separate study by Nargotra and co-workers (Mehra *et al.*, 2016a), MD simulation was used to elucidate the probability of inhibitor binding at the allosteric site of the SK enzyme. SK, which catalyses the phosphorylation of 3-OH-shikimic acid (in the presence of ATP as co-substrate), is one of the key enzymes in the shikimate pathway responsible for the biosynthesis of chorismate, an important precursor for the subsequent biosynthesis of common aromatic amino acid residues (Phe, Trp, Tyr) and secondary metabolites essential for the MTB survival (Herrmann and Weaver, 1999; Parish and Stoker, 2002). As the best SK inhibitor, 5489375 showed uncompetitive inhibition for SK and noncompetitive inhibition for ATP in *in vitro* experiments. Thus, it is suggested that the inhibitor may have potentially bound at another binding site. To investigate this, the inhibitor was docked to the common allosteric site of three different protein complexes, i.e., the Michaelis complex, complex A and the product complex, as predicted by SiteMap, and each complexes was subjected to a 10 ns MD simulation. Interestingly, the inhibitor was found to be displaced out of the initial binding cavity of the Michaelis complex and complex A to the surface of the protein after about 4 ns and 1 ns of simulations, respectively. Whilst the inhibitor remained in the initial binding cavity of the product complex throughout the simulation, with low ligand RMSD (~ 5 Å) and RMSF values (< 3.5 Å). This suggests that the inhibitor is likely to bind to the allosteric site only after the reaction products are formed. Additionally, further MD analysis demonstrated that hydrogen bond and hydrophobic contacts formed between residues Arg43, Ile45 and Phe57 of the enzyme and the inhibitor for at least 23% of the simulation time, suggesting that the binding of the inhibitor at the allosteric site of the SK enzyme is stabilised by these residues.

Preparation of Target Structure for Structure-Based Drug Design and Discovery Studies

A protein undergoes continual conformational changes under physiological conditions while maintaining its overall fold, i.e., 3D structure. A snapshot of a protein typically provided by the X-ray crystal structure would not be able to account for the continual conformational changes although the overall topology of the folded state remains conserved. During docking using a protein's crystal structure, a slightly different orientation of even a single side chain in the binding site of the protein can significantly influence docking results (Zhao and Caflisch, 2015). To address this issue, MD simulations have been used to generate multiple conformers of target proteins, where ensembles of snapshots from MD simulations of target proteins such as InhA enzymes from wild-type and 116T and 121V mutants, were selected for docking with inhibitors (Cohen *et al.*, 2011; Khan *et al.*, 2017). The idea is to model the explicit flexibility of the target proteins, which is postulated to be more accurate and realistic than rigid crystal structure for docking. Not surprisingly, the mode of ligand binding, the number of interacting residues and the ligand binding affinity in this models varied significantly from the docked ligand on the crystal structure, with more interacting residues observed for the ensembles. For example, Ser94 and Gly96 residues are also found to be crucial for strong drug-InhA interactions, in addition to the Lys165 and Ile194 residues, but these interactions (involving Ser94 and Gly96) were not observed in the crystal structure (PDB: 2NSD) (Khan *et al.*, 2017; He *et al.*, 2007).

Generation of ensembles of target proteins with MD simulations for docking, however, is not possible when no 3D structure is available. This is especially true for novel targets where the experimental 3D structures are usually yet to be determined. In TB, this include enzymes involved in the biochemical pathways for the biosynthesis of peptidoglycan, a key component of the MTB cell wall, such as the enzymes for the formation of UDP-GlcNAc from D-fructose-6-phosphate (GlmS, GlmM, GlmU), UDP-MurNAc from UDP-GlcNAc (MurA, MurB), UDP-MurNAc-tetrapeptide from UDP-MurNAc, and UDP-MurNAc-pentapeptide from UDP-MurNGlyc (MurC-MurF) (Alderwick *et al.*, 2015). Although these enzymes have long been characterised biochemically, not much work has been done on them until recently when the incidence of multi-drug resistant TB is getting more rampant. As such, homology models of the target enzymes such as MurA (Babajan *et al.*, 2011), MurC (Anuradha *et al.*, 2010), MurD (Arvind *et al.*, 2012), MurG (Fakhar *et al.*, 2016), Muri, MraY, DapE, DapA, Alr and Ddl (Fakhar *et al.*, 2016) were built based on the 3D structure of the template proteins in the PDB database with high sequence similarities to the target. Homology models, however, generally require further refinement, and this is usually performed by MD simulations on a 10–100 ns timescale on explicit environment (Fan and Mark, 2004). In these models, 5–20 ns of MD simulations were performed for refinement, and root mean square

deviation (RMSD) and radius of gyration (Rg) were calculated and compared to their corresponding templates or previous states to confirm the stability of these models. Subsequent use of these models for docking highlighted certain important residues for ligand and substrate binding and selectivity (e.g., Gly125, Lys126, Arg331 and Arg332 in MurC; His192, Arg382, Ser463 and Tyr470 in MurD) (Anuradha *et al.*, 2010; Arvind *et al.*, 2012). In addition, 10 potential inhibitors for MurG have been identified from the MD-refined model (Saxena *et al.*, 2017), although none of these observations have been validated by *in vitro* experiments.

Evaluation of the Binding Interactions, Stability and Free Binding Energies of Protein-Ligand Complexes

Apart from preparing protein structures for structure-based studies, MD simulations are also often used in tandem with docking studies to further optimise the docking poses of anti-TB drug candidate as well as identified hits from virtual screening or *in vitro* assays. One example is a study by de Jonge and colleagues, who have used energy minimisation (EM) – MD simulation cycles (60 cycles of alternate 1500 EM iterations and 1500 MD iterations of 0.2 fs) to optimise docking pose for each stereoisomer of the lead inhibitor of MTB ATPase, R207910 (de Jonge *et al.*, 2007). Computed interaction energies of the optimised docking poses showed that the RS stereoisomer bound more strongly to MTB ATPase than the SR, RR and SS stereoisomers, which are in agreement with the observed antimicrobial activity.

MD simulations are also commonly used to explore stability of ligand binding modes to various TB protein targets such as GyrB (Maharaj and Soliman, 2013; Islam and Pillay, 2017), GlgE (Sengupta *et al.*, 2015), MurG (Saxena *et al.*, 2017), GlmU (Mehra *et al.*, 2016b; Soni *et al.*, 2015), LipU (Kaur *et al.*, 2018), MtbA (Maganti *et al.*, 2015), MbtI (Maganti *et al.*, 2016), sHSP16.3 (Jee *et al.*, 2017), ASADH (Kumar *et al.*, 2015), AAC (Prabu *et al.*, 2015), PknG (Singh *et al.*, 2015), Polyphosphoglutamate synthetase (Hung *et al.*, 2014) and α subunit Trp synthase (Naz *et al.*, 2018). Generally, as low as 2 ns (Maharaj and Soliman, 2013) and as high as 60 ns (Jee *et al.*, 2017) of MD simulations have been performed for this purpose, although 10 ns simulations are also seen being carried out for most protein-ligand complexes. To evaluate the stability of the protein-ligand complexes, convergence of RMSD and root mean square fluctuation (RMSF) plots of the protein backbone (e.g., C α atoms) and ligands' non-hydrogen atom are monitored. In some studies, radius of gyration was also calculated to determine the changes in protein compactness and conformation upon ligand binding (Islam and Pillay, 2017; Kaur *et al.*, 2018). Less commonly, variability in potential energies and important ligand/residue distances were measured in order to evaluate the stability of the docked complex (Maharaj and Soliman, 2013; Kumar *et al.*, 2015).

A stable ligand-protein complex observed from MD simulations is important as it allows a better prediction of a ligand binding mode on the target protein which are dynamic in nature. More importantly, this information allows the identification of moieties critical for ligand-protein interaction. Generally, there are two common approaches that have been used to extract such information from stable trajectories of MD simulations involving TB protein target-inhibitor complexes. In the first approach, an average structure from the stable trajectories is calculated followed by visualisation of the protein-ligand interactions via a molecular visualisation software. This approach is illustrated in a study by Saxena and colleagues who compared the protein-ligand interactions of the average structure from stable MD simulations (20–25 ns) to the initial docked pose, and identified two of the seven residues (i.e., Leu290 and Met310) at the binding site of MurG that retained close interactions with the lead molecules as key residues important for MurG inhibition (Saxena *et al.*, 2017).

The second approach is by calculating the hydrogen bond occupancy involving the active site residues of the protein target and the ligand throughout the MD simulations. For examples, Kumar and colleagues discovered that the hydrogen bond occupancy for β -AFP ligand and inhibitor, NSC4862 on MTB-ASADH during whole MD simulation are 81.4% and 54.3% with Arg99 and 43.8%; and 30.3% with Arg249, respectively; suggesting that these highly conserved active site residues are critical for ASADH inhibition (Kumar *et al.*, 2015). Similarly, Mehra and colleagues revealed that Ser320, Thr321 and Asp424 of MTB Proteasome involved in hydrogen bond interactions with G7650246 in more than 25% of the simulation times, while residues Ala434, Arg439, Ala451 and Lys464 of GlmU have at least 20% hydrogen bond occupancy with inhibitor 5810599, suggesting that these residues are important for Proteasome and GlmU inhibitions, respectively (Mehra *et al.*, 2015, 2016b).

In addition to obtaining protein-ligand stability and interaction information, MD simulations are also being used for free energy calculation and free energy decomposition analysis of various anti-TB inhibitors. These are performed on stable MD trajectories of ligand-receptor complex, using Molecular Mechanics Poisson-Boltzmann Surface Area (MM-PBSA), Molecular Mechanics Generalised Born Surface Area (MM-GBSA) or Linear Interaction Energy (LIE) approximation approaches. The use of MM-PBSA and MM-GBSA to estimate ligand-binding affinities are not new (Genheden and Ryde, 2015). For instance, Kamsri and colleagues calculated the binding free energies of diphenyl ether inhibitors (compounds 17, 18, 19 and 29) in InhA using MM-PBSA method based on 125 snapshots from last 1 ns of MD trajectory; this calculated energies were found to agree well with the experimentally determined ΔG (Kamsri *et al.*, 2014b). Similarly, Kumar and colleagues used MM-GBSA to calculate binding free energy from 200 frames of the last 20 ns of 100 ns production run and successfully identified two InhA inhibitors (TB2, TB10) with better energies than the control ligand, (5-hexyl-2-(2-methylphenoxy)) phenol (IC_{50} = 5 nM). These compounds were found to give >90% inhibition of H37Rv strain of MTB in BACTEC assay (Kumar *et al.*, 2017). On the other hand, Timmers and colleagues demonstrated that calculation of free energy binding from MD trajectories with LIE method (which is a semi-empirical approach that combines advantages of free energy perturbation and thermodynamics integration) is as accurate as MM-PBSA or MM-GBSA methods, with only 0.7 kcal/mol difference in the calculated binding energy of an inhibitor (compound 9) on cytidine deaminase (MtCDA) compared to the experimental value (IC_{50} = 151.74 μ M, ΔG_{exp} = – 5.2 kcal/mol, ΔG_{LIE} = – 5.9 kcal/mol) (Timmers *et al.*, 2012).

MD simulations have also been used to build quantitative models to predict binding affinities of e.g., aryl acid-AMP bisubstrate inhibitors of MbtA (Labello *et al.*, 2008). The model was constructed based on correlation between the LIE-estimated free energy binding from MD trajectories and the experimental indicator of binding affinity. Interestingly, this model was able to predict the binding affinity of an unknown related compound, N-6-cyclopropyl-2-phenyl-SaI-AMS, with predicted binding affinity = 1.6 nM versus experimental K_i of 0.7 nM. In a separate study, snapshots from MD trajectories have been used to generate structure-based e-pharmacophore model of CmaA1 based on the interactions of the active site residues with the natural ligands SAM and SAHC (Choudhury *et al.*, 2015). These models were found to be able to correctly identify up to 17 out of 23 reference compounds screened compared to only one for model generated from crystal structure.

Example of Successful MD Study

MD simulation has been used to understand the mechanism of resistance of INH towards its target, i.e., InhA. Wahab and co-workers had investigated the mechanism of mycobacterial resistance against isoniazid, focusing on the active site of MTB InhA (Wahab *et al.*, 2009) (Fig. 6(A)). This work was initiated with molecular docking simulation of isonicotinic acyl-NADH (INADH; the active form of isoniazid) in both the wild-type and resistant-type (S94A) of InhA (Fig. 5(B)), followed by MD simulation to further investigate the dynamics behaviour of INADH in InhA. Interestingly, higher flexibility at the binding site was observed for resistant-type InhA compared to the wild-type, as reflected by the disruption of hydrogen bond network, and lesser hydrophobic, van der Waals and electrostatics interactions in the former. The smaller free energy binding, ΔG in resistant-type also correlates well with the interactions analysis where higher fluctuation caused by INADH was observed. In addition, the existence of water-mediated hydrogen bond network with INADH in the wild-type further supports the hypothesis that the conversion of prodrug isoniazid into its active form, INADH, is mediated by KatG on InhA. Further study (Choong and Wahab, 2011) on the dynamics of INADH in other reported single point mutations of InhA (I16T, I21T, I21V, I47T, V78 and I95P) (Fig. 6(B); Rouse *et al.*, 1995; Milano *et al.*, 1996; Miesel *et al.*, 1998), showed that the reduced side chain volume in all InhA mutants has provided more rooms for structural fluctuations in both INADH and mutated InhA residues, thus decreasing the INADH binding affinity, in agreement with the experimental findings on low-level isoniazid resistance for InhA mutants (Fig. 6). Although the resistance to isoniazid has been known for 70 years, there are still rooms to improve our understanding to this phenomena by using MD simulations in combination of other physical methods such as ultrafast two-dimensional infrared spectroscopy as presented recently by Hunt and co-workers (Shaw *et al.*, 2017) and the knowledge from the simulations could be exploited further in searching for potential inhibitors as alternative to isoniazid.

Using MD to understand the underlying INH mechanism of action, has allowed Venugopala and co-workers to venture into discovering InhA inhibitors by combining this technique with docking calculation (Khedr *et al.*, 2017). *In silico* docking trisubstituted indolizine analogues along with resazurin microplate assay screening were conducted to screen on the

indolizine analogues. 50 ns MD simulation was conducted on the top selected hit from docking and assay results. Their assay results had shown that by substitution of ethyl group at second position of indolizine nucleus, it exhibited activity against susceptible and multidrug-resistant strains of MTB at concentration of 5.5 and 11.3 $\mu\text{g/mL}$, respectively. Correlation was found for compound with ethyl substitution at second position of indolizine nucleus on the docking data with highest free binding energy of $\Delta G - 24.11$ (kcal/mol). With MD simulation, MM-PB/GBSA results had also indicated well correlation with docking as well as the experimental data. Besides, Pongpo and co-workers had also adopted MD simulation (Kamsri *et al.*, 2014a) that further extended the work with 3D-QSAR to understand the structural basis of diphenyl ether derivatives on InhA (Kamsri *et al.*, 2014b). The volume of the binding cavity and the surface area of the compounds were correlated with the inhibitory activity. Their results indicated that smaller binding site cavity with higher surface area of the compound served to increase the inhibitory activity. Larger binding site cavity may imply less fitting of the compound to the binding site and thus leading to the loss of activity. Besides, energy decomposition of important residues such as Phe149, Tyr158, Met161, Met199, Val203 were analysed using MM-PBSA method. In their work later Kamsri *et al.* (2014b), 3D-QSAR approach was used to identify the key features of diphenyl ether derivatives for InhA inhibition were and again MD was used to study the binding energy using MM-PBSA calculation.

As a prodrug, isoniazid needs to be activated by KatG enzyme of which the mutations, has also been correlated with the INH resistance. To date, there is no crystal structure of isoniazid bound to KatG MTB. Using molecular docking of INH on KatG followed by 100ns MD simulation has allowed the identification of INH binding site on MtKatG whereby only one site (Site-1) resulted in conformational change when INH bound to it suggesting it as the main INH binding site (Srivastava *et al.*, 2017). This information is crucial such that future INH targeting inhibitors should avoid being metabolised by KatG enzyme. Theoretically, MD can be used to assess whether or not a new potential inhibitor of InhA can be metabolised by KatG from the prediction of the binding interaction of the molecule with the enzyme. Avoiding being metabolised by KatG enzyme will prevent drug resistance due to mutation or deletion of this enzyme in MTB.

The ability of MTB to go into a dormant state has caused a treatment nightmare as such targeting an enzyme important to the survival of MTB in the dormant state is a good alternative in finding potential TB drugs. Isocitrate lyase (ICL), is one of the key (Fig. 4(A)) enzymes involved in energy generation in MTB via glyoxylate shunt. It is one of the important targets in dormant phase MTB. Research on ICL especially on structure based drug design is still popular and ongoing. However, due to its small polar active site, only moderate ICL inhibitors have been reported (Mdluli *et al.*, 2014), thus opportunities to understand the structure, dynamics and stability of this enzyme for drug design cannot be understated.

To date, both *apo*- and *holo*- forms of ICL have been reported (PDB ID: 1F61; 1F8I; 1F8M; 5DQL). To understand the functional behaviour of ICL in its different subunit forms, MD simulations of ICL have been carried out (Lee *et al.*, 2017). Briefly, ICL in its dimer form was studied in three different conditions, i.e., one apo and two complex forms in order to investigate the open and close conformation of both bound and unbound states with its substrate. Analysis from the MD trajectories suggested that the open-close behaviour of the entrance of ICL active site is highly dependent on the type of ligands as free energy calculations showed a stronger binding affinity for isocitrate (gate-opening) than glyoxylate or succinate (gate-closing) (Fig. 7(A-D)). A total of four residues were suggested to be the possible points for cleavage of isocitrate at the C2-C3 bond by nucleophilic attack.

Investigation on ICL is also the centre of attention for Shukla and co-workers who were interested to understand the effects of mutation of this enzyme (Shukla *et al.*, 2015) using MD approach. The effect of flexibility of ICL on the functionality of this enzyme was first investigated by a single point mutation of His180 (Fig. 4(B)). Observations on the dynamic changes of ICL revealed a disrupted interaction between His180 and Tyr89, which affects the tetrameric assembly important for the enzymatic activities. Subsequent site-directed mutagenesis work on a different binding site residue, Phe345 (Shukla *et al.*, 2017a; Fig. 4(B)), discovered that the flexibility of the enzyme in the binding site was increased for the mutant type, resulting in the decreased stability of the whole enzyme.

Point mutation on H46A (Shukla *et al.*, 2018) using MD were also conducted. Interestingly, although the point mutation site (H46A) is far away from the binding site of ICL, they found that the conformation at the binding site and the volume of binding site cavity were altered, and the loss of enzyme activity was observed. They predicted that this could be due to the loss in structural plasticity and collective motion. This postulation is reflected by the time-dependent secondary structure analysis. In their extensive MD simulation on both wild-type and mutant-type (H46A), significant secondary structure changes were observed where the catalytic cleft of the wild-type was found to adopt a higher numbers of turn and bend with the formation of 3-helices. The number of these loops, turns and 3-helices structures were significantly lower in the mutant-type, indicating a more rigid structure in the mutant. In addition, with H46A mutation, the residue interaction network at the active site was also found to lead to the changes in the active site environment. These observations suggest that apart from the active site residues, His46, which is distance away from the active site cleft, can also affects the ICL functionality, and thus is also a promising site to be exploited (other than the active site) in discovery of novel ICL inhibitors.

Again, the information generated by MD simulations have been used in *in silico* identification of potential inhibitor of ICL from the ZINC database (Shukla *et al.*, 2017c). To compare the dynamics of the protein upon ligand binding, MD simulations were performed, and principle component analysis (PCA) was calculated for the stable trajectories (last 20 ns) to predict large concerted motions during ligand binding to ICL. Values for the first few eigenvectors of apo-ICL were found to be higher than the ICL-ligand complexes, suggesting that the apo-ICL has more correlated motions, and thus less stable than the ICL-ligand complexes. In other words, ligand binding stabilised the complex. Additionally, 2D projection of the trajectories for PC1 and PC2 for ICL-

Fig. 7 Enzyme active site views of holo ICL dimer at 30 ns MD simulation. (A) Complex_ICL (with the presence of glycoxylate and succinate) active site 1, (B) Complex_ICL (with the presence of glycoxylate and succinate) active site 2, (C) Complex_ICL (with the presence of isocitrate only) active site 1 and (D) Complex_ICL (with the presence of isocitrate only) active site 2. Loops were highlighted in colours with respective active site 1/active site 2 residue number. Red: residues 91–93/518–520; Yellow: residues 104–114/531–541; Green: residues 154–159/581–585; Pink: residues 185–196/612–623; Cyan: residues 230–234/657–661; Purple: residues 285–289/712–716; Ice-blue: residues 314–319/741–746.

ZINC2111081 complex revealed that it occupied less space in the phase space than other compounds, with well-defined cluster, suggesting that ZINC2111081 formed more stable complex with ICL.

The above scenarios although limited to two enzymes can easily be extended to other MTB drug targets of which some of them have been covered in the previous section. Clearly, the application of MD in drug design is of immense importance, however, it should be noted that the potency of inhibitors is only the first step in drug discovery. Other aspects of drug development such as toxicity, pharmacokinetics and pharmacodynamics are also important determinants for the inhibitors to succeed in clinical trials. Limitations of MD must also be taken into consideration. Improvement of force fields, length of the simulations, enhanced sampling, inclusion of entropy effects, allosteric modulation and solvation effects should also be given special emphasis in the MD study relating to drug discovery.

Concluding Remarks

From the evaluation of the fundamental understanding of conformation alteration, functionally significant interaction as well as mechanism of action of lead compound on potential drug targets in MTB, MD simulation no doubt is one of the most time and cost-effective tools to be used. Moreover, it is also able to enhance the drug-receptor binding mode, as well as predicting drug binding affinity at better accuracy, which is important in understanding the structure-activity relationship in drug discovery. Additionally, combining molecular insights from MD simulation with other *in silico* approaches such as high-throughput screening of potential hit, in-depth atomic interaction studies using QM/MM as well as further validation by conventional experiments would certainly help to further enhance the efficiency in discovery of new anti-TB drugs for the benefits of the mankind.

Acknowledgement

We thank Dr Thaigarajan Parumasivam for his generosity in providing the SEM image of the H37Rv strain (ATCC 25618) of *Mycobacterium tuberculosis*. Special thanks to Dr Lee Yie Vern for her permission to reuse and readapt the ICL MD trajectories. Choong YS would like to acknowledge Universiti Sains Malaysia Bridging Grant (304/CIPPM/6316018).

Introduction

Carbohydrates (also known as sugars or glycans) provide the primary source of energy for living organisms, are used as structural elements, and are the essential components of cofactors (such as ATP, NADPH, etc), glycoproteins and polynucleotides (Quiocho, 1989). These carbohydrates interact with diverse types of proteins and are the basis of many biological processes, both normal and pathological ones including fertilization, immune response, cancer, etc. These interactions also play key roles in several cell adhesion phenomena, among them the attachment of parasites, fungi, bacteria, and viruses to host cells; an indispensable step for the infection (Karlsson, 1991; Ofek *et al.*, 2003). In numerous cases, the protein-carbohydrate interaction may not be a straightforward event but only an initial step that may trigger complex signaling cascades (De Schutter and Van Damme, 2015). Carbohydrates can play so many different roles in molecular recognition due to their ability to generate a broad range of structurally diverse moieties from few monosaccharides that are connected by various linkage types (Audette *et al.*, 2003). Additionally, these carbohydrates can be extremely branched, therefore allowing oligosaccharides to offer nearly a limitless diversity of structural variations.

The significance of protein-carbohydrate interactions in regulating several physiological processes has been acknowledged since decades now. However, the molecular basis underlying such interactions has emerged in recent times. Application of X-ray crystallography to study protein-carbohydrate interactions is the main technique involved, but carbohydrates are quite challenging to crystallize because their inherent flexibility may not be compliant to structural analysis. They may even avert crystallographic studies if this flexible nature on the protein surface hampers the arrangement of crystal contacts, which normally prompts their enzymatic elimination as part of the sample preparation for crystallization (Agirre *et al.*, 2017). Therefore, to get the conformational and dynamical information; the application of NMR spectroscopy was utilized. Because of the typical features of carbohydrates, it is established that relaxation NMR parameters should be integrated with computational methods in order to define the structural characteristics of carbohydrates in an explicit manner. Therefore, to better understand the structure/activity relationships of protein-carbohydrate interactions, interdisciplinary approaches are probably the best options that can be applied to study these complexes (Jiménez-Barbero *et al.*, 1999).

Other traditional approaches, including the hemagglutination inhibition assay (Lis and Sharon, 1972), enzyme-linked lectin assay (McCoy *et al.*, 1983), surface plasmon resonance (Duverger *et al.*, 2003) and isothermal titration calorimetry (Dam and Brewer, 2002), have been used to investigate carbohydrate recognition by proteins. Regardless of their successful application to elucidate the details of protein-carbohydrate interactions, such techniques are labor-intensive and may have certain restraints in terms of requirements of large amounts of pure carbohydrate samples, protein size, solubility, or ease of crystallization, besides the cost (Zhang *et al.*, 2016). Because of these shortcomings the conventional methods seem inapplicable as high-throughput analytic methods (Park *et al.*, 2007). With the introduction of carbohydrate microarrays in 2002 (Wang *et al.*, 2002; Fukui *et al.*, 2002) the limitations of the requirements for low sample quantities and attaining high-throughput parallel screening were overcome (Puvirajesinghe and Turnbull, 2016). However, limited number of efficient analysis tools to extract relevant information limits the use of glycan microarray data (Malik *et al.*, 2014). Rapid advances in the method, in addition to its application in investigation of protein-carbohydrate interactions, it is now possible to successfully discriminate the selective interactions of carbohydrates with bacteria, viruses and eukaryotic as well as live cell responses to immobilized glycans (Puvirajesinghe and Turnbull, 2016). Recently, hydrogen/deuterium exchange mass spectrometry (HDX-MS) was applied to investigate the sites for ligand binding within carbohydrate-binding proteins (Zhang *et al.*, 2016). No doubt these experimental methods are indispensable to fully understand protein-carbohydrate interactions; however, they have certain challenges associated with them such as weak binding affinity and synthetic complexity of specific carbohydrates (Ng *et al.*, 2015). Additionally, other limiting factors that hinder these studies include cost, time and labor. To overcome these challenges, several computational methods to study these types of interactions have been proposed and applied to identify carbohydrate binding sites in proteins.

These computational methods can be divided into three categories: (i) knowledge- or empirical-based methods; (ii) machine-learning based methods; and (iii) molecular dynamics based methods. Here, we discuss these methods that have been applied to study protein carbohydrate interactions.

Knowledge- or Empirical-Based Methods

A three-dimensional (3D) structure of a protein-carbohydrate complex obtained *via* X-ray crystallographic or NMR based methods is desirable to understand the interactions involved. Because of the limitations of these experimental methods to determine such complexes, knowledge-, empirical-, and structure-based methods have been developed for the prediction of glycan interacting

residues from the 3D structures. (Taroni *et al.*, 2000) calculated six parameters [relative accessible surface area (RSA), residue propensity, solvation potential, planarity, hydrophobicity, and protrusion] of glycan binding sites on a set of 19 non-homologous carbohydrate binding proteins using PATCH program (Taroni *et al.*, 2000). These parameters were then utilized to resolve if the surface patch under scrutiny is a carbohydrate-binding site. This analysis revealed that RSA, protrusion index and residue propensity were the three best parameters that differentiate the carbohydrate binding sites from other surfaces. Evaluation of this method on two independent datasets (Test set1, which does not show any homology to the main dataset, and, Test set2 which consists of structures homologous to either the main data set or the Test set1) showed the overall prediction accuracy of 65%, which was a higher success rate for enzymes as compared to lectins.

In another work, empirical rules of the spatial distribution of protein atoms around carbohydrate-binding sites were used for prediction (Shionyu-Mitsuyama *et al.*, 2003). This method also requires a known 3D structure of a protein-carbohydrate complex to construct the empirical rules, and subsequently, these rules were utilized to search the carbohydrate binding sites on the target protein. The empirical rules were constructed using a non-redundant data set of 80 protein-carbohydrate complexes and the prediction system was tested on an independent dataset of 50 experimentally derived complexes. This method worked better for Galactose, Glucose and *N*-Acetylglucosamine binding sites as compared to Mannose binding sites. The attributes or properties used between the above-mentioned two methods is different in a sense that the former method (Taroni *et al.*, 2000) uses amino acid propensity whereas the latter system employs the spatial distribution of amino acid residues at the glycan-binding sites (Shionyu-Mitsuyama *et al.*, 2003).

Sujatha and Balaji (2004) developed a program called COTRAN to search for the potential galactose-interacting sites in proteins. They utilized 18 protein-galactose complexes belonging to 7 non-homologous families and investigated the galactose-binding sites. This method utilizes a combination of the inferred geometrical characteristics in addition to structural features [for example, accessible surface area (ASA) and secondary structure] to detect a possible galactose-binding site signature with very high accuracy.

Recently, Zhao *et al.* (2014) developed a structure-based function-prediction method called SPOT-Struc that recognizes carbohydrate-binding proteins (Zhao *et al.*, 2014). This method predicts interacting residues by structural alignment program SPAlign (Yang *et al.*, 2012) and knowledge-based statistical potential [distance-scaled finite-ideal gas reference state (DFIRE)] is used for predicting the binding affinity scoring. In this method, a template library of 523 (T523) carbohydrate binding proteins (CBPs) was derived from PROCARB (Malik *et al.*, 2010) database. Additionally, a positive binding domain dataset consisting of 113 CBPs (BD113) and a negative dataset of 3442 non-CBPs (NB3442) were constructed at 30% sequence identity cutoff. The prediction system works by first aligning the target structure against the templates (T523 dataset) by structural alignment tool SPAlign, where the structural similarity score is calculated by a scoring function called SP-score (Yang *et al.*, 2012). In case the SP-score is larger than a given threshold, the model for the complex structure between the query protein and template carbohydrate is generated by substituting template protein structure with the query structure in the template complex structure. The model complex structure is further used to calculate the binding affinity by the DFIRE (Zhou and Zhou, 2002; Yang and Zhou, 2008). The query is predicted as a CBP if the binding affinity is above a certain threshold; else non-CBP. Finally, the predicted structures from SPOT-Struc are utilized for the prediction of interacting residues. If any heavy atom of an amino acid is within a contact distance of < 4.5 Å from any heavy atom of the carbohydrate was defined as a binding site. A leave-one-out cross-validation (LOOCV) method on BD113 and NB3442 datasets achieved the MCC of 0.63 and 0.58 for the prediction of CBPs and carbohydrate-interacting residues, respectively at 52% sensitivity and 79% positive predictive value (PPV) of CBP prediction. A comparable level of accuracy was observed for two additional datasets of bound (HOLO) and unbound (APO) structures of CBP.

An approach based on the energy function for identifying the carbohydrate binding sites has also been proposed (Gromiha *et al.*, 2014) that uses AMBER force field with GLYCAM06 (Kirschner *et al.*, 2008) parameters for calculating the interaction energy between the atoms in a protein and the bound carbohydrate. The residues that are involved in interactions with carbohydrates have been analyzed in terms of binding segments which is based on the number of sequential binding residues in protein sequences. For instance, a 4-residue binding segment has a region of four back-to-back binding residues. This study generated several statistics, including incidence of amino acid residues at different interaction energies, binding propensity scores of amino acid residues in protein-carbohydrate complexes, contribution of various atom types in these types of interactions, inclination of dipeptides and tripeptides around the binding sites, highlighting the significance of stronger atomic level contributions from carbohydrates as compared to proteins.

Machine Learning (ML)-Based Methods

ML-based methods have been successfully applied in both sequence- and structure-based methods. Although, ML-based approach is the same but the input features or attributes are different between sequence- and structure-based methods (Fig. 1). In general, different features are extracted from the protein sequences or structures (including knowledge-based information) and are used as inputs for ML methods, and the binding site is obtained from them. Extensive use of ML has been applied to address various biological questions. The biggest advantages of ML is that it can deal with multiple features or attributes at the same time and capture the hidden relationships among them, which are otherwise challenging to derive with knowledge- or empirical-based methods (Manavalan *et al.*, 2014; Manavalan and Lee 2014a; Manavalan *et al.*, 2017b,c; Alpaydin, 2014; Bastanlar and Ozuysal, 2014; Nilsson, 1996). In the following subsections, we discuss sequence- and structure-based methods in which ML has been applied to study protein-carbohydrate interactions.

Fig. 1 An overview of ML-based prediction framework. It involves four different stages: (i) construction of the datasets; (ii) extraction of features from the sequence or structures and the selection of important features; (iii) development of the prediction models using various ML methods; (iv) final model selection based on their performances in training dataset and independent dataset.

Fig. 2 A summary of important Molecular simulations (MS) and Molecular docking (MD) parameters that need to be considered while studying protein-carbohydrate interactions by using molecular dynamics methods. The coordinates of PDB ID 3MAN was used to generate the figure by using VMD (Humphrey *et al.*, 1996).

Structure-Based Prediction Methods

The first structure-based method using ML was proposed in 2009, where they applied support vector machine (SVM) to predict the glucose binding sites (Nassif *et al.*, 2009), whose optimal features were identified using random forest (RF) algorithm. This study revealed that in addition to carboxylate residues, the significance of ordered water molecules and ions might participate in deciphering glucose-binding specificity. Additionally, the relevance of high concentration of negatively charged atoms that make direct contacts with the glucose was highlighted. Using LOOCV, this method achieved 8.11% error, 89.66% sensitivity and 93.33% specificity with a dataset of 43 glucose- and 68 non-glucose-binding sites. Similarly, mannose binding sites were also predicted by using RF by extracting at least 15 features (e.g., charge, hydrophobicity, hydrogen bonding, etc.) both at the atomic as well as residue level (Khare *et al.*, 2012). This method achieved an accuracy of 96% and 94% with respect to individual feature and combined features, respectively. However, the applicability of this prediction model remains to be determined because a very small dataset (only 11 protein-mannose complexes) was used for the prediction model development. The common feature of two structure-based methods and the knowledge-based method by Sujatha and Balaji is their specificity for a particular type of sugar (e.g., glucose, mannose or galactose).

ML algorithms have also been applied to predict non-specific carbohydrate binding sites in proteins. A method called InCa-SiteFinder, which utilizes the amino acid propensities and van der Waals energy of a protein-probe interaction for searching or predicting the non-covalent inositol and non-specific glycan binding sites on the protein structures (Kulharia *et al.*, 2009). This method used a dataset of 375 protein-carbohydrate complexes (which is larger compared to the earlier studies) to derive amino acid propensities. InCa-SiteFinder uses a two-step procedure to predict the carbohydrate binding sites. The first step employs an energetic grid-based approach (Laurie and Jackson, 2005) to detect potential sites on the protein with a higher possibility of being a binding site, whereas in the next step it uses potential sites information along with the amino acid propensities to predict the region of carbohydrate binding sites. The performance of InCa-SiteFinder was assessed by a single parameter, tau (τ) which in turn is a product of two individual parameters, precision (P) and coverage (C) (*i.e.*, $\tau = P \times C$). This method performed reasonably well when tested on 80 protein-ligand complexes. Furthermore, this method achieved 98% specificity and 73% sensitivity with an overall error rate of 12%, when tested on dataset of 40 known drug-like compound binders as well as 40 known carbohydrate binders to predict the carbohydrate binding site locations and to further distinguish both the types from one another.

Another method was developed which was different as compared to earlier described methods in a sense that it utilizes a unique encoding scheme of the 3D probability density maps representing the distributions of 36 non-covalent interacting atom types around protein surfaces (Tsai *et al.*, 2012). The 36 atoms represent 30 atom types from proteins, 5 from carbohydrate ligands, and 1 from the water. A ML model was trained for all the 30 types of protein atoms. In ML models, each attribute is representing the normalized distance-weighted sum of the 3D probability density for the one interacting atom type (out of 36) on the protein surface. Three types of ML algorithms were used to predict the carbohydrate binding sites: (a) Artificial neural network (ANN), (b) SVM, and (c) ANN with bootstrap aggregation (ANN_BAGGING). For training as well as testing, only atoms on protein surfaces that have solvent accessible area of larger than 0 were included. These ML models were trained to learn the patterns of the attributes to discriminate between binding- and non-binding site atoms. Furthermore, the probability of each amino acid atom assumed to be within a glycan binding site was scaled into a prediction confidence level between 0 and 1. Surface atoms of protein with greater certainty levels from the predictors were grouped to output provisional glycan-binding patches. The predictors were validated on a non-redundant dataset of 497 proteins with known binding sites for carbohydrate by a 10-fold cross-validation, and additionally tested on an independent dataset of 108 proteins. ANN_BAGGING method produced the best result with an average Matthews correlation coefficient (MCC), sensitivity, and specificity of 0.45, 0.49, and 0.97 respectively, when compared to other two methods.

In general, the above methods are dependent on the protein's local structural descriptors and hence are of little significance in case of the unavailability of their 3D structures.

Sequence-Based Prediction Methods

It is well known that the frequency of mutations at functional sites during evolution is much lesser as compared to the other parts of a protein (Livingstone and Barton, 1993; Zvelebil *et al.*, 1987). The difference in amino acids at these functional sites can be represented in the form of sequence conservation patterns by using matrices of position-specific variations, known as profiles (Gribskov *et al.*, 1990), or by statistical methods, such as Hidden Markov Models (HMMs) (Krogh *et al.*, 1994; Eddy, 1998). Sequence homologies (local as well as global) can be detected by these methods or by more sensitive approaches such as Position Specific Iterative (PSI) blast program (Altschul *et al.*, 1997) search, thereby implying putative functions and functional sites, by comparison. Sequence-based methods exploiting ML have become indispensable to the functional annotation of proteins since decades (Kneller *et al.*, 1990; Ahmad and Sarai, 2005; Liu and Rost, 2004; Firoz *et al.*, 2011). In addition to many other disciplines of bioinformatics, ML methods have been extensively employed in the prediction of interaction sites between two biomacromolecules. In general, ML refers to the modifications in systems that carry out tasks such as recognition, diagnosis, planning, robot control, prediction, etc., which are linked with artificial intelligence (AI) (Nilsson, 1996). The main objective of ML is to program computers to use model data or previous experience to resolve a problem at hand (Alpaydin, 2014). The rapid upsurge in biological data as well as the processing potential and storage capacity of computers has led to enhanced developments in the field of ML (Bastanlar and Ozuysal, 2014). Given a protein sequence which is expected to interact with another molecule (DNA, RNA, carbohydrates, ligands, etc.) the challenge of ML is to guess which amino acid residues might be involved in the interactions (Wang and Brown, 2006).

In sequence-based methods, there are two types of approaches that can be used to encode input protein sequences (Hwang *et al.*, 2007): (a) Single sequence approach – Each amino acid residue is converted into a 20 bit vector and propagated through a ML model along with its neighboring residues (Gallet *et al.*, 2000; Ofra and Rost, 2007) as well as combining additional structural information (Ahmad and Sarai, 2005). (b) Evolutionary information (EI) – This approach utilizes residue conservation and EI (position specific scoring matrices (PSSMs)) by using PSI-BLAST (Altschul *et al.*, 1997). In this method, the target sequence is searched for homology against a protein database and generates a profile for the input sequence in the form of scoring matrices, which is then supplied to a ML algorithm such as neural networks or SVM for prediction. Sequence profiles of neighboring residues and structural information have increased the prediction accuracy (Hwang *et al.*, 2007; Wang and Brown, 2006; Zhou and Shan, 2001; Kuznetsov *et al.*, 2006).

Several developments have been made for the prediction of protein-protein interaction sites (Zhou and Shan, 2001; Ofra and Rost, 2007; Li *et al.*, 2012; Fariselli *et al.*, 2002), prediction of DNA (Ahmad and Sarai, 2005; Carson *et al.*, 2010; Ofra *et al.*, 2007) and ligand binding sites in proteins (Passerini *et al.*, 2006; Shu *et al.*, 2008; Chen *et al.*, 2014; Suresh *et al.*, 2015). Recognizing the significance of protein-carbohydrate interactions, Malik and Ahmad (2007) developed the first sequence-based method using ANNs to predict carbohydrate binding sites in proteins (Malik and Ahmad, 2007). They trained two separate neural network architectures using evolutionary profiles of protein sequences and information from single sequences to predict carbohydrate binding sites. The network using EI achieved 87% sensitivity of prediction at 23% specificity whereas with the single sequences, 68% sensitivity and 55% specificity for all carbohydrate-binding sites was obtained. The authors proposed that the prediction accuracy can be improved further when their method trained with the larger size of the dataset in the future. Although, this method was developed using the dataset of 40 protein-carbohydrate complexes, it showed an improved performance when tested on a dataset generated by Sujatha and Balaji (2004). The method was later implemented in the form of a web server, CBS-Pred (Malik *et al.*, 2010) and can be accessed at see “Relevant Websites section”. The work triggered interest within the scientific community which resulted in the development of new sequence-based methods to predict carbohydrate binding sites by employing ML. Most of these methods focused on a specific type of sugar. For example, SVM based classifiers were developed to predict mannose interacting residues (MIRs) from the primary sequences of mannose binding proteins (MBPs) (Agarwal *et al.*, 2011). The method employs several modules such as similarity-based module, SVM based module which uses binary profile of patterns, SVM module using EI, and a module on the basis of composition profile of patterns (CPP) or local composition for predicting mannose binding residues in proteins. Among these different modules, the CPP based SVM method outperformed other modules by achieving a maximum MCC of 0.61. A method called MOWGLI was also developed to predict MIRs that uses an ensemble of base classifiers using PSSM (Pai and Mondal, 2016). In this method, the base classification algorithm was developed by exploring RF and SVM trained by various subsets of training data set of 128 mannose binding proteins using 10-fold cross-validation. The performance of the method was measured on a separate test dataset of 29 mannose binding proteins and achieved an accuracy of 92%. A standalone version of this method is available at see “Relevant Websites section”. With the exception of CBS-Pred (Malik *et al.*, 2010), the type of interacting carbohydrate is known in all of the above-mentioned methods. However, it becomes more difficult when such information is unknown well in advance. Another sequence-based method that integrates sequence and predicted structural features for the prediction of nonspecific carbohydrate binding sites was developed (Taherzadeh *et al.*, 2016). The method in addition to EI, uses sequence derived structural information (such as solvent accessibility and secondary structure), seven physico-chemical features (volume, steric parameter, isoelectric point, hydrophobicity, polarizability, alpha-helix and beta-sheet probability) of amino acids, information about the disordered residues, and the protein length as the input features. The most effective features were selected to build a classifier based on SVMs and the method achieved an area under receiver operating characteristic curve (AUC) of 0.78 and 0.77 for 10-fold cross-validation and independent test.

Recently, a method was developed which classifies sugars into acidic and non-acidic sugars and discriminates between their amino acid composition at the binding sites (Banno *et al.*, 2017). These characteristics were then used to design two predictors viz, an acid sugar binding predictor and a non-acidic sugar binding predictor. Additionally, a third predictor was developed that combined the output of the two above mentioned predictors. The dataset used to develop this method consists of 369 sugar-binding proteins, 136 acidic sugar-, and 270 non-acidic-sugar-binding proteins. A PSSM profile of sugar-interacting sites and their neighboring residues were employed to predict the sugar binding sites by using SVM. The method achieved an AUC of 0.787 and 0.752 for the acidic and non-acidic sugar binding predictors, respectively, on the basis of a 5-fold cross-validation. In case, the characteristic nature of sugar was unknown or is known to be non-acidic, the combined predictor performed best with AUC of 0.760. The method is freely available for download as a standalone program (see “Relevant Websites section”).

To date, there are three structure-based methods and five sequence-based methods publicly available for the prediction of carbohydrate binding sites. The web server link and other details are provided in Table 1.

Advantages of sequence-based methods over structure-based methods

Due to the advancement in sequencing technology, the number of sequences deposited in the protein sequence database is growing exponentially, which has outpaced the experimental determination of protein structures. This has created a big void between the number of protein sequence entries and their experimentally determined 3D structures. This sequence-structure gap is expected to increase further in the future. As a result, sequence-based bioinformatics tools have become indispensable for researchers as they are not dependent on a costly and time-consuming procedure of experimental determination of protein structures (Hwang *et al.*, 2007). Moreover, sequence-based tools have attractive leverage in managing high-throughput data generated in the fast-growing proteomics field. Although, sequence-based methods have several advantages, the prediction accuracy is slightly lower than the structure-based methods. Their accuracy may become better once the key question to identify the best features that may help in improving the prediction of these binding sites is addressed.

Table 1 List of available methods to predict carbohydrate-binding sites in proteins. The methods highlighted in bold font and normal fonts respectively denote the structure- and sequence-based methods

Method	Link	Carbohydrate specificity	Status (As of 12th Oct 2017)	Reference

Table 2 Summary of the parameterization protocols for some of the well known force-fields dedicated to carbohydrates and an example application of these force fields in simulating the protein-carbohydrate complexes

Force field	Parameterization protocol used for the development					Example application
	Vdw terms	Torsion terms	1,4-Scaling (Elec/vdW)	Unique atom types for α - and β -anomers	Unique charge sets for α - and β -anomers	
GLYCAM	AMBER PARM94	Fit to QM rotational energy curves	X	x	✓	Mishra <i>et al.</i> (2014)
CHARMM	CHARMM22		X	✓	x	Mallajosyula <i>et al.</i> (2015)
OLPS-AA-SEI	OPLS-AA		✓	✓	✓	Kony <i>et al.</i> (2002)
GROMOS	GROMOS-45A4		X	✓	✓	Vital De Oliveira (2014)

Note: For detailed review of these force fields, interested readers are referred to Fadda, E., Woods, R.J., 2010. Molecular simulations of carbohydrates and protein-carbohydrate interactions: Motivation, issues and prospects. *Drug Discov. Today* 15, 596–609 and Xiong, X., Chen, Z., Cossins, B.P., *et al.*, 2015. Force fields and scoring functions for carbohydrate simulation. *Carbohydr. Res.* 401, 73–81 of the reference section.

In general, structure-based methods always perform better than the sequence-based methods. This is mainly due to the following reasons: (i) structure-based methods contain features derived from both the sequences as well as from the structures. Basically, it includes a sequence-based method and improving the corresponding algorithm by adding the structural information (ii) the information/features derived from the structures is more accurate when compared to the sequences. However, this method requires a 3D structure as an input, but again solving a 3D structure is not simple, and requires lot of time and effort. As a result, sequence-based methods are preferred.

Molecular Dynamics Based Methods

Force Fields

Molecular dynamic simulation studies are performed to gain a possible observation of the progression of motions in the molecular systems at atomic level (Hansson *et al.*, 2002). These are based on the deterministic propagation of various forces interim on a molecular system. These computer simulation processes have provided us with powerful tools to deeply investigate the detailed molecular interactions. For a successful simulation, we need an accurate force field which could provide a realistic portrayal of the systems. The development of accurate force-fields for protein-carbohydrate interactions has been an area of active research. It is a very laborious task to develop an accurate force field compatible to deal with the carbohydrates (Xiong *et al.*, 2015). Over the last couple of decades a large number of force fields capable of dealing with carbohydrates were developed. These force fields were developed by outspreading the classic force fields making them to deal with different carbohydrates.

Here we are listing some of the major force fields specifically developed to handle carbohydrates. These force fields are either dedicated ones for carbohydrates or they are an extension of the previously used force fields with changes implemented. GLYCAM06, CHARMM36, 53A6GLYC, GROMOS and OPLS-AA-SEI (Scaling Electrostatic Interaction), are some of the major carbohydrate force fields (Table 2). These force fields were developed for better consistency for simulating the larger systems including nucleic acids, proteins, and lipids.

GLYCAM06

This force field is compatible for a large group of carbohydrates, in addition to acetylated amino sugars, neuraminic acid, and iduronic acid (Kirschner *et al.*, 2008). This force field is widely used for modeling the protein-carbohydrate complexes in addition

to the modeling of carbohydrates, glycolipids and glycoproteins (Tessier *et al.*, 2008; DeMarco and Woods, 2008). GLYCAM06 is compatible with the AMBER force field (Fadda and Woods, 2010) and comprises of parameters appropriate for the simulation of carbohydrates (Kirschner *et al.*, 2008). These parameters of GLYCAM06 can be effectively used for simulating carbohydrates of different conformations and ring sizes (both oligosaccharides and monosaccharides). Using appropriate file-conversion tools, GLYCAM06 is fit for use in other simulation packages (Dejoux *et al.*, 2001). Additionally, GLYCAM06 is loaded with parameters developed by considering a test set of 100 molecules from different chemical families, like carboxylates, alcohols, amides, esters, hydrocarbons, ethers and other molecules of diverse functional groups which have been fitted to quantum-mechanical data (Perez and Tvaroska, 2014). Several stereoelectronic effects influencing the bond and angle variations at the anomeric carbon atom have been parametrized in this force field (Biarnès *et al.*, 2010). These features allow it for mimicking the ring inversion observed in glycosidic monomers during several catalytic events. The comparison of the GLYCAM06 derived results with experimental findings suggested that this force field correctly reproduces the rotational energies and carbohydrate features (Guvench *et al.*, 2009).

CHARMM36

The force field for handling carbohydrates is one of the modifications added to CHARMM all-atom biomolecular force fields (Hatcher *et al.*, 2009; Guvench *et al.*, 2008; Guvench *et al.*, 2009; MacKerell *et al.*, 1998, 2004). This updated force field is embedded with parameters allowing the simulation of unsubstituted oligosaccharides as well as monosaccharides. A large number of revisions for handling carbohydrates have been implemented in the upgraded version of this force field. These updates extend the capability of this force field for handling the five-membered sugar rings and oligosaccharides. The same hierarchical parameterization process and handling of 1,4 nonbonded interactions are exploited to guarantee complete compatibility with other CHARMM biomolecular force fields (MacKerell *et al.*, 1998). The current parameterization of CHARMM makes it compatible for simulating the monosaccharides (i.e., glucopyranoses and diastereoisomers (Guvench *et al.*, 2008) and aldo- and fructofuranoses (Hatcher *et al.*, 2009) and for unsubstituted oligosaccharides (Guvench *et al.*, 2008).

OPLS-AA-SEI

OPLS-AA Scaling of Electrostatic Interactions also known as OPLS-AA-SEI, an upgraded version of OPLS-AA biomolecular force field with parameters for carbohydrates for the improved prediction of its conformational changes (mainly Φ and Ψ angles) (Kony *et al.*, 2002). In comparison to OPLS-AA, OPLS-AA-SEI has been reported to be more accurate in terms of reproducing quantum mechanics (QM) relative energies.

GROMOS

Two different versions for dealing with carbohydrates have been developed. The first one is the classic GROMOS 45A4 and the advanced one is GROMOS 53A6GLYC. The GROMOS 45A4 is compatible for dealing with mono-, di-, oligo-, or polysaccharides (Lins and Hunenberger, 2005) and comprises of advance and better parameters designed specifically for carbohydrates. It also consists of parameters for handling mono- and oligosaccharides on the basis of pyranosides. GROMOS 53A6GLYC is another improved version with more advanced features set for simulating the carbohydrates in explicit-solvent. This version allowed appropriate depiction of the best possible conformation out of all 16 aldohexopyranose-based monosaccharides (Pol-Fachin, 2017).

Molecular Docking

As compared to protein-ligands, the interaction of a protein and a carbohydrate is more dynamic (Fadda and Woods, 2010). The affinities of these interactions are more likely dependent on several relatively weak interactions. In protein-carbohydrate-interactions, CH- π interactions and hydrogen bonds are the main types of interactions (Spiwok *et al.*, 2005). Molecular docking of proteins and their interacting carbohydrates is still a challenge, due to the inaccuracy of scoring functions for accurate prediction of their interaction. At present, very limited number of carbohydrate specific scoring functions have been developed and reported. It is a great need to develop a scoring function capable of accurately predicting the correct binding pose, along with binding free energy of the complex.

Some major docking tools like AutoDock (Morris *et al.*, 2008), Glide (Friesner *et al.*, 2004), GOLD (Verdonk *et al.*, 2003), and FlexX (Cross, 2005) are in use for studying protein-carbohydrate interactions. In a recent study the ability of these docking tools were compared and assessed. The top ranked poses generated by each of these tools was compared to its already known crystal counterpart. This comparison highlighted the weakness and strength of each tool. The findings of this study revealed the best results were obtained by GLIDE (Agostino *et al.*, 2009). Though the finding of this study shows the RMSD of the predicted results were in range with the experimentally determined structures, however, the best predicted results do not correspond to the experimental data.

The findings of several studies conducted on protein-carbohydrate interactions gives an impression that it is still extremely challenging to develop accurate and efficient methods for calculating the binding affinity of such complexes (DeMarco and Woods, 2008). In the last decade, a significant increase in the application of molecular docking methods for studying protein-carbohydrate interactions was observed (Reina *et al.*, 2008; Takaoka *et al.*, 2007; De Geus *et al.*, 2009; Chen and Shoichet, 2009; Gomez *et al.*, 2016; Bakkers *et al.*, 2016; Mompean *et al.*, 2017; Walker *et al.*, 2017). For a successful docking, an efficient searching algorithm along with a robust scoring function is critically required (Hill and Reilly, 2008). In case of protein-carbohydrate

interactions the bridging water molecules and CH- π interactions are also key role players (Raju *et al.*, 2009; Spiwok *et al.*, 2005; Vandenbussche *et al.*, 2008). The more commonly used molecular docking programs had certain limitations in dealing with these important factors involved in the interaction of carbohydrates to proteins.

Limitations of traditional molecular docking tools

It is very challenging for the regularly used docking programs to identify the shallow carbohydrate binding sites. In addition, compared to other organic molecules, carbohydrates are significantly more flexible (Kerzmann *et al.*, 2008; Imberty, 1997). These widely used molecular docking programs are mainly developed for analyzing the binding of small molecules. The use of these traditional docking methods is not capable to accurately predict the orientation of carbohydrate within the binding site and the relative binding affinity of this conformational pose (interaction energy). There are several factors which are responsible for their inability to deal with the carbohydrates. Unlike small ligands, carbohydrates are extremely flexible, and consist of several hydroxyl groups (DeMarco and Woods, 2008). The presence of wide hydrogen-bonding networks along with the formation of CH- π contacts are the major reasons which restrict these traditional docking tools from accurately predicting carbohydrate-protein complexes (Spiwok, 2017; Grant and Woods, 2014).

Moreover, the explicit treatment of the solvent is required for capturing the hydrogen bonds between carbohydrates with water (Nivedha *et al.*, 2016, 2014; Kirschner and Woods, 2001). Some of the essential parameters required for the efficient docking of protein-carbohydrate interactions are summarized in Fig. 2. Due to these major challenges, it is difficult to correctly predict the carbohydrate binding sites and their affinities using traditional docking methods.

Advancement towards designing computational methods for protein-carbohydrate docking

Several approaches were made towards preparing a better method for accurate prediction of protein-carbohydrate interactions. Studies performed on carbohydrate docking used the scoring functions which were customized either by recalibrating the existing terms (Laederach and Reilly, 2003) or by including few more additional functions capable of modeling some of the specific features of protein-carbohydrate interactions (Kerzmann *et al.*, 2006). Kerzmann *et al.* (2006) specifically designed a scoring and an energy function termed as Sugar-Lectin Interactions and DoCKing (SLICK), for predicting the binding poses and free energy calculations for carbohydrates to proteins. This scoring function accounts for CH- π interactions, solvation effects, hydrogen bonds, van der Waals interactions and electrostatics. The binding free energies predicted using SLICK showed high accuracy when compared to the experimental binding energies. This is due to the calibration of the parameters for the empirical energy function. This function is available in the molecular modeling package of BALLDock (see "Relevant Websites section") (Gauto *et al.*, 2013). The glycosidic linkages within oligosaccharides are the critical source of flexibility. In previous studies, scoring functions were customized for carbohydrate docking. This customization was done by either recalibration of existing terms or the annexation of supplementary functions capable of modeling the protein-carbohydrate interactions. The SLICK scoring function comprises of an energy term for CH- π stacking interactions and was calibrated by using a set of lectin-carbohydrate complexes (Kerzmann *et al.*, 2006). Later it was found that incorporating the explicit water molecules during the docking of carbohydrates (Samsonov *et al.*, 2011) as well as inclusion of the placement of hydroxyl groups of carbohydrates in water site positions (Gauto *et al.*, 2013) leads to improvements in docking accuracy. Inclusion of the conformational preferences of oligosaccharides within a scoring function additionally enhances the accuracy and efficiency of carbohydrate docking. Recently, Carbohydrate Intrinsic (CHI) energy functions assign relative energies to the torsion angles of the glycosidic linkages. The distribution of glycosidic torsion angles in protein-carbohydrate complexes obtained by CHI-energy profiles resembled with those obtained from the Protein Data Bank (PDB) (Nivedha *et al.*, 2014).

Reports also suggest the inclusion of Carbohydrate Intrinsic (CHI) energy functions in carbohydrate docking algorithms would be beneficial (Nivedha *et al.*, 2014). The CHI-energy function was incorporated into the AutoDock Vina (ADV), and was termed Vina-Carb (VC) (Trott and Olson, 2010; Nivedha *et al.*, 2016). For the development of Vina-Carb, a dataset consisting of 29 apoprotein structures and 101 protein-carbohydrate complexes were used. Findings show that the addition of CHI-energy function within the Vina-Carb increases its success rate from 55% to 74% (Nivedha *et al.*, 2016). However, while dealing with the ligands that partially extend into solution, Vina-Carb was unable to reproduce the experimental findings (Nivedha *et al.*, 2016). This is an issue which needs to be addressed for a successful development of scoring function for accurately describing the protein-carbohydrate interactions. Recently, RosettaCarbohydrate Framework was developed for the modeling and docking of oligomeric and polymeric carbohydrate ligands and glycoconjugates (Labonte *et al.*, 2017). The framework can handle the sampling of glycosidic bonds, side-chain conformations, and ring forms, and it can also use a glycan-specific term within its scoring function.

Applications

Among the currently available methods for the prediction of carbohydrate binding sites, two each from the sequence- and structure-based methods have been presented here (Table 3). Briefly, CBS-Pred has been used in three such studies and predicted three aromatic residues involved in polysaccharide binding (Park *et al.*, 2014), lipopolysaccharide binding amino acids in several peptides (Brzozowska *et al.*, 2015), and mannose interacting residues in CrataBL glycoprotein (Pol-Fachin, 2017). SPRINT-CBH was also used to predict the mannose interacting residues of CrataBL, and a carbohydrate binding tyrosine residue of an unknown gene PA5359 from *Pseudomonas aeruginosa* (Gunasekera *et al.*, 2017). In case of structure-based methods, ISMBLab_PCA has been used most commonly. For example, it was used for the prediction of carbohydrate binding sites in a toxin, pneumolysin

Table 3 Application of different carbohydrate binding site prediction methods. The methods highlighted in bold are structure-based and require a 3D structure of a protein for prediction

<i>Method</i>	<i>Types of carbohydrates under investigation</i>	<i>Reference</i>
CBS-Pred	Polysaccharide Monosaccharide Lipopolysaccharide	Park <i>et al.</i> (2014) Pol-Fachin (2017) Brzozowska <i>et al.</i> (2015)
SPRINT-CBH	Carbohydrate binding Monosaccharide	Gunasekera <i>et al.</i> (2017) Pol-Fachin (2017)
InCa-SiteFinder	Druggable pocket	Dharra <i>et al.</i> (2017)
ISMBLab_PCA	Monosaccharide Sialyl Lewis X, Lewis B and mannose LewisX and Sialyl LewisX	Pol-Fachin (2017) Lawrence <i>et al.</i> (2015) Shewell <i>et al.</i> (2014)

(Shewell *et al.*, 2014; Lawrence *et al.*, 2015). In addition to the sequence-based prediction, the mannose binding sites of CrataBL (Pol-Fachin, 2017) were also predicted by using ISMBLab_PCA.

In the case of docking, over the past two decades various attempts have been made to dock carbohydrates to their protein partners (Imberty, 1997; Bitomsky and Wade, 1999; Mulakala and Reilly, 2005; Gohier *et al.*, 1996). The docking ability of several softwares was also compared to calculate the binding affinity of *Ralstonia solanacearum* lectin (RSL) (Mishra *et al.*, 2012). More recent docking methods have also been applied to investigate the interactions of carbohydrates and their interacting proteins. Being published in 2016, a limited number of studies highlighting the application of Vina-Carb are available. For example, a recent study by Gómez *et al.* (2016) demonstrated the use of Vina-Carb for docking of hexasaccharide into the endo- β -1,4-xylanase (Xyl2) active site. Since the methods for specifically docking the carbohydrates are just beginning to appear, it will be a while before their accuracy could be tested for a wide range of carbohydrates.

Future Directions

The information about the factors, which direct or inhibit the binding of a carbohydrate to an amino acid, is believed to exist in the evolutionary profile of the sequence as well as the identity and structure of amino acid residues in the neighboring environments of potential carbohydrate binding sites (Malik and Ahmad, 2007). Although several computational methods have been developed for the protein-carbohydrate interactions, yet none of these methods can offer satisfactory predictions given the diversity of carbohydrates. Methods dealing with specific types of carbohydrates might be promising but they have a limited practical application, whereas the predictors for non-specific carbohydrates may have a broader application, however, at the cost of accuracy. Another issue with the existing methods is that there is no consensus definition for a binding site. The binding and non-binding residues are defined based on a certain distance cut-off. Therefore, it is necessary to optimize the distance cut-off threshold because the introduction of higher cut-off may introduce many false positive and false negative in the dataset (Ding *et al.*, 2010). Currently, the existing sequence-based methods use similar features, small datasets for their prediction model development, no systematic feature selection protocol was employed to quantify the important features, and none of the methods explored different ML methods using the same dataset to identify the most appropriate one for this problem. The key question, however remains to derive or develop a novel feature beyond the PSSM profile, predicted secondary structure and solvent accessibility, along with the exploration of ML-based methods and systematic feature selection protocol, which will be helpful to improve the prediction accuracy and stimulate further development in this field. Additionally, the carbohydrate binding residues predicted from ML-based methods could be utilized to design molecular dynamics based studies. Similar approaches were suggested for studying protein–DNA interactions (Kaufman and Karypis, 2012). Such approaches may help to increase the overall carbohydrate-binding sites prediction performance.

Conclusion

Experimental identification of protein-carbohydrate complex is very difficult, expensive and often time-consuming, and, therefore, the development of computational methods is necessary to predict the carbohydrate-binding sites from the given uncharacterized protein sequence. The expeditious increase of the structure databases offers an opportunity to apply knowledge-based or molecular dynamics based approaches for prediction, but these methods offer limited utility and cannot be used if the 3D structures of proteins are unavailable. Therefore, the development of more accurate sequence-based predictors is the need of the hour.

Introduction and Background

Protein–nucleic acid interactions play key roles in many biological processes. In a large group of such events, the binding of the proteins to their respective nucleic acid counterpart affects some regulatory outcome such as transcriptional and translational regulation and protein synthesis. Activation of an immune system in response to pathogen invasion is another example in which specific nucleic acid compositions of pathogens are recognized as the first step in a complex biological pathway. Approximately 21% of proteins are denoted as nucleic acid binding, based on UniprotKB/SwissProt database (Boutet *et al.*, 2007). Nucleic acid binding proteins are mostly composed of at least one DNA/RNA-binding domain where the interfacing with amino acids take place in specific or nonspecific manner.

DNA-binding proteins (DBPs), such as transcription factors, DNA polymerases, DNA ligases, some Toll like receptors, and methyltransferases can be represented by various DNA-binding domains carrying different molecular functions. Common DNA-binding domains include the zinc finger, helix-turn-helix, leucine zipper, and helix-loop-helix domains. On the other hand, many RNA-binding proteins are important for posttranscriptional regulation (Glisovic *et al.*, 2008) and the regulation of gene expression (Ray *et al.*, 2013). One or more RNA-binding domains facilitate the formation of protein–RNA interfaces. This includes RNA recognition motifs such as the K Homology motif, RGG box motif, and DEAD/DEAH box domain (Lunde *et al.*, 2007).

While proteins adopt different mechanisms for both DNA- and RNA-binding activity, general methods of detecting binding residues, before the crystal structure of a complex is solved, are useful to comprehend the molecular recognition capacity and interface mechanics and hence designing molecular interventions. Experimental methods like X-ray crystallography and nuclear magnetic resonance have been used to determine the structures of numerous protein–nucleic acid complexes and these structures have greatly contributed to the understanding of what constitutes as protein–nucleic acid interfaces and favorable modes of interactions in the structural context.

Such experimental methods lead to the steady growth in the numbers of protein–nucleic acid complexes deposited into the Protein Data Bank (Rose *et al.*, 2017). As of September 2017, the database contains entries for 4317 and 2290 protein–DNA and protein–RNA complexes, respectively. Experimental methods of determining protein–nucleic acid interactions are time-consuming and expensive. Furthermore, experimental approaches will not be able to cope with the ever-increasing number of protein sequences requiring annotation for their potential nucleic acid binding ability. It is also not possible to solve the crystal structure of every homolog for every NA-binding protein, even though small sequence-level changes may significantly alter the interaction dynamics. Hence, computational platforms for prediction of nucleic acid binding sites from sequence can provide an alternative that can be just as reliable to analyze protein–nucleic acid interactions.

Over the years, a number of computational tools have been developed for the prediction of DNA/RNA-binding residues in sequence data. Here, we survey a selection of such tools that are available as web services. Our focus in this article is to compare web servers in terms of: (i) the data they use as the input during training and subsequent use by researchers; (ii) the engine that drives their predictions; (iii) the kind of output they generate; and (iv) the performance levels claimed during their publications, some of which we have benchmarked for a quick estimate of their relative advantage. Such reviews are also available in the literature as part of other studies but with a growing number of new tools and perspectives that can be developed, we feel that an overview in a nutshell for reference purposes is needed. We have structured our discussion into four parts. First, we take a look at the user interaction of the tools for binding site predictions. Particularly, we discuss the user inputs and output formats in each of the available tools. Subsequently, we look at the techniques used in developing these prediction methods, including the datasets and the features for data driven models. Then, we describe the performance scores and evaluation strategies of binding site prediction tools and discuss the challenges therein. Finally, we present some case studies and discuss how users can get the best out of multiple prediction tools available over the web.

Computational Tools for Nucleic Acid Binding Prediction: The User Perspective

Detection of amino acids that interact with nucleic acids from protein sequence can be most useful as well as challenging when no structural information is available. A number of computational platforms have been developed for predicting DNA-binding residues from sequence, such as DP-Bind (Hwang *et al.*, 2007), DQPred-DBR (Chai *et al.*, 2016), TargetDNA (Hu *et al.*, 2016), and DRNAPred (Yan and Kurgan, 2017). Some of the methods to predict RNA-binding site/residues from protein sequence include DRNAPred (Yan and Kurgan, 2017), AaRNA (Li *et al.*, 2014), PRIdictor (Tuvshinjargal *et al.*, 2016), RNABindRPlus (Walia *et al.*, 2014), RNABindR (Walia *et al.*, 2012), and SRCPred (Fernandez *et al.*, 2011). AaRNA and SRCPred are also able to predict dinucleotide contacts. These methods allow for the rapid detection of amino acids that are thought to be interacting with nucleic acids. In some cases, users are interested in specific DNA or RNA-binding predictions and the use of different tools may provide overlapping predictions. Some tools are developed with this deconvolutionary objective in mind. Table 1 summarizes the list of selected tools for the prediction together with their descriptions while Table 2 provides a comparison of the features and capability of each service.

Server Inputs and Formats

Most prediction methods require a protein sequence in the FASTA format or single code amino acid sequence as the query by either pasting them or uploading the file(s). The ability of several programs – DRNAPred, RNABindRPlus and RNABindR to rapidly predict DNA-binding residues for a batch of protein sequences provide them an advantage in contrast with other prediction methods. Amino acid sequences of desired proteins can be culled from protein chains in the Protein Data Bank (Rose *et al.*, 2017) or protein sequence databases like NCBI RefSeq (Pruitt *et al.*, 2007) and SwissProt (Bairoch and Apweiler, 2000). In an unlikely scenario, when users only have a PDB-formatted protein structure, various programming scripts and PDB-related web servers can be used to extract amino acid sequence from SEQRES records found in the PDB file, such as ccPDB (Singh *et al.*, 2012), PDBFINDER (Touw *et al.*, 2015) and PISCES (Wang and Dunbrack, 2003) web servers.

Output and Average Time for Computations

The time for the computation to be completed is often influenced by the list of queries submitted to the server at a given time. A prediction conducted for a single protein sequence could take a few minutes on average to be completed, where the output is either submitted to an email address or displayed on the web server directly upon job completion. The predictions conducted by these web servers mostly return binding propensities, with the predicted probability values and binary label for each amino acid in the sequence, commonly termed as “0” for nonbinding or “1” for binding.

Methodologies Behind Binding Site Prediction Tools

Training Datasets

Protein–nucleic acid contact data

Protein structure datasets play a crucial role in the development of prediction methods for protein–nucleic acid interfaces. Methods that predict nucleic acid binding residues are commonly trained and tested upon a set of nucleic acid binding residues with a distinct definition of contacts. The contact data are derived from proteins known to bind to nucleic acids, either from protein–nucleic acid complexes or annotated DNA/RNA-binding proteins. Protein structures are retrieved from the Protein Data Bank (Rose *et al.*, 2017) and certain filters are applied before training them. In most cases, refinements are carried out based on (1) structure quality, that is, X-ray crystallography determined structures at high resolution; and (2) sequence identity with distinct cut-off values to generate nonredundant structures/folds. The datasets generated by each prediction tool might also differ from one another according to different exclusion criteria such as exclusion of proteins with inadequate residue lengths (Li *et al.*, 2014; Walia *et al.*, 2012), and the removal of residues with missing coordinates (Hwang *et al.*, 2007; Yan and Kurgan, 2017).

Different annotations of protein–nucleic acid interactions at the residue level have been used to generate a sample pool containing binding residues for the training of prediction methods. The binding interfaces are defined by the maximal distance between amino acids to any atom from the nucleic acid. One often-used definition for a binding residue is that any amino acid

Table 1 Computational programs for sequence-based DNA/RNA-binding residue prediction

Prediction	Service/ program	Description
DBR	DP-Bind	A sequence-based prediction method using three different machine learning methods to generate a consensus prediction of DNA-binding residues (Hwang <i>et al.</i> , 2007); (http://lcf.rit.albany.edu/dp-bind/)
	DQPred-DBR	An evolution-based prediction method using dynamic model to detect DNA-binding residues (Chai <i>et al.</i> , 2016) (http://www.inforstation.com/webserver/DQPred-DBR/predict.html)
	TargetDNA	A SVM-based method using weighted evolutionary profiles to target protein–DNA binding residues (Hu <i>et al.</i> , 2016) (http://csbio.njust.edu.cn:8080/TargetDNA/)
DBR/RBR	DRNAPred	A combined prediction method for DNA- and RNA-binding residues using sequence and structural features based on protein sequence (Yan and Kurgan, 2017) (http://biomine.cs.vcu.edu/servers/DRNAPred/)
RBR	AaRNA	A sequence and structure-based prediction method for RNA-binding propensity using homology modeling and neural networks (Li <i>et al.</i> , 2004) (https://sysimm.ifrec.osaka-u.ac.jp/aarna/)
	PRIdictor	A sequence-based method to predict protein–RNA interfaces from RNA and protein sequences according to global and local features (Tuvshinjargal <i>et al.</i> , 2016) (http://bclab.inha.ac.kr/pridictor/pridictor.html)
	RNABindRPlus	A combined homology and SVM-based prediction method using evolutionary profile to locate RNA-binding residues (Walia <i>et al.</i> , 2014) (http://ailab1.ist.psu.edu/RNABindRPlus/)
	RNABindR	A protein–RNA interface prediction tool that combine naïve Bayes and SVM methods using both sequence and structural features from protein sequence (Walia <i>et al.</i> , 2012) (http://ailab1.ist.psu.edu/RNABindR/)
	SRCPred	A PSSM-based prediction tool for RNA dinucleotide contacts in protein sequence using neural networks (Fernandez <i>et al.</i> , 2011) (http://ccbb.jnu.ac.in/shandar/servers/srcpred/)

residue with a distance of less than 3.5 Å to any nucleic acid atom is treated to be in the interface. This definition has been used by DBSPred, SDCPred, DBS-PSSM, DRNAPred, AaRNA, and SRCPred web servers (Ahmad *et al.*, 2004; Andrabi *et al.*, 2009; Ahmad and Sarai, 2005; Yan and Kurgan, 2017; Li *et al.*, 2014; Fernandez *et al.*, 2011) with Fernandez *et al.* (2011) additionally integrating the annotation of RNA-binding motifs retrieved from the SCOR database (Hubbard and Thornton, 1993). Tuvshinjargal *et al.* (2016) (PRIdictor), on the other hand, defined protein–nucleic acid interaction in a more specific way that involved three different types of intermolecular forces including hydrogen bonds, hydrophobic forces and water-mediated contacts – As retrieved from Nucleic acid–Protein Interaction Database (Kirsanov *et al.*, 2013).

Protein sequences

Most prediction methods rely on experimentally determined crystal structures of protein–nucleic acid complexes. Such high resolution datasets provide binding or nonbinding information at a single residue level. On the other hand long stretches of amino acids are annotated as NA-binding in sequence datasets, which is useful in discriminating binding domains. Some NA-binding site prediction methods have also used such annotations to evaluate the prediction at the proteome scale. Examples of this are the use of nonredundant protein sequences from NCBI in the work of Hwang *et al.* (2007) and human protein sequences from UniProt database and several curated databases as adopted by Yan and Kurgan (2017). Programs that implement a homology-based method like DQPred-DBR and RNABindPlus generate their training sets of known binding residues obtained from sequence homologs of the query proteins searched against the Protein–RNA Interface Database (PRIDB) (Lewis *et al.*, 2011) and SwissProt (Bairoch and Apweiler, 2000), respectively.

Prediction Algorithms

Machine learning methods

Machine learning methods are commonly employed on other problems of sequence-based structure and function predictions in proteins (Al-Shahib *et al.*, 2007), for example, secondary structure prediction (Wang *et al.*, 2016) and prediction of interfaces for protein–protein complexes (Sun *et al.*, 2017). These methods have also been adapted to predict protein–nucleic acid interactions (Hwang *et al.*, 2007; Chai *et al.*, 2016; Hu *et al.*, 2016). Prediction models based on these machine learning methods are trained and tested with benchmark datasets of known class labels (binding or nonbinding) and a variety of prediction features usually derived from sliding windows over the whole sequence. These methods include neural networks (Li *et al.*, 2014; Ahmad and Sarai, 2005; Ahmad *et al.*, 2004; Fernandez *et al.*, 2011), support vector machines (SVMs) (Hwang *et al.*, 2007; Chai *et al.*, 2016; Hu *et al.*, 2016; Tuvshinjargal *et al.*, 2016; Walia *et al.*, 2014, 2012), naïve Bayes (Walia *et al.*, 2012); random forest (Ma *et al.*, 2011), logistic regression models (Yan and Kurgan, 2017; Walia *et al.*, 2014), and hidden Markov models (Yan and Kurgan, 2017; Li *et al.*, 2014).

Artificial neural network (ANN) models typically contain three *layers*- the input, hidden, and output layers - where each layer is made up of a designed number of *nodes* according to the features used for prediction (Lancashire *et al.*, 2009). SVM is another popular technique adopted to predict nucleic acid binding residues, where it was shown to outperform other machine learning methods apparently due to its ability to develop more robust models. An SVM-based prediction model is based on trained parameters of a kernel, which assigns class labels to new data. In the case of binding residue prediction, the prediction model is trained and tested with sets of annotated binding residues (positive class samples) and/or nonbinding residues (negative class samples), where they learn to classify objects from known data and compare with expected output in a supervised manner.

Most prediction methods on the web receive a set of amino acids in the form of a vector as the input, yield a binding propensity for individual residue in the sequence that indicates probability of target residue to be in a particular class, and at given thresholds generate a binary label for each residue.

Alignment-based methods

Alignment-based methods can be useful to predict protein–nucleic acid interactions when similar NA-binding sequences are available for the query sequence, since binding residues are often conserved among similar proteins. As an example of such approaches, Walia *et al.* (2014) combined HomPRIP, a homology-based method and SVM to predict RNA-binding residues in protein sequences. They defined the conservation of residues as an interface conservation (IC) score, that is, the degree of conservation of residues in the query protein as compared to its sequence homologs. These scores were derived from pairwise sequence alignments. The program first searches for sequence homologs using BLAST against PRIDB, calculates an IC score for each sequence homolog, and later assigns putative binding residues based on the known binding residues annotated in homologs. Another prediction program, DQPred-DBR, generates a dynamic sample to train the SVM-based prediction model, which includes a set of binding residues derived from sequence homologs of the query protein, searched against the SwissProt database. Alignment-based methods are intuitive and powerful but are greatly dependent on similarity thresholds. Lower similarity thresholds result in a lesser number of initial samples for prediction. When no homologs can be detected for the query protein, there is no choice but to use a method developed using a sliding window approach, employed in almost all the other methods described in this article.

Discriminative Features in Data Driven Models

A combination of features obtained from protein sequences are used to train and evaluate the performance of prediction models. These features include evolutionary information, sequence features within a window, structural features, and physical or biochemical features. Commonly used features for protein–nucleic acid interactions that are extracted from sequence only information include evolutionary information from PSSM, neighboring residues, accessible surface area (ASA), and secondary structure prediction.

Sequence features

Evolutionary conservation

Evolutionary conservation in the form of position specific scoring matrices (PSSMs) essentially indicates the probability of each residue to be conserved in a specific position of the sequence (Ahmad and Sarai, 2005). However, it goes beyond simple conservation as it also accounts for specific substitution patterns, which provides it with clues to characterize each position. These features have been used with the assumption that most binding sites are conserved to some extent. The substitution profiles of specific NA-binding residues should reflect a particular trend so as not to lose the binding capacity and this pattern can be captured by a machine learning model such as a neural network. Thus, PSSM is perhaps the most popular representation of sequence information for predicting binding sites. A large number of prediction programs use evolutionary information in the form of PSSM, including DP-Bind, DQPred-DBR, TargetDNA, RNABindPlus, RNABindR, and SRCPred.

PSSM profiles are generally obtained from PSI-BLAST searches of the query protein against a sequence database and a Nx20 matrix is obtained representing the substitution probability of individual residues to all other amino acid types in a given length of the sequence. Ahmad and Sarai (2005) proved that evolutionary information from PSSM is a powerful feature to discriminate binding and nonbinding residues and this was similarly suggested by Hwang *et al.* (2007) where the accuracy of prediction increased when using PSSM profiles alone or when combined with structural features.

Sequence neighborhood

Residue nearest neighbors can influence prediction, with the assumption that a network of residues is required for the protein to bind to nucleic acid residues (Yan and Kurgan, 2017; Miao and Westhof, 2015). Thus, residues with high propensity sequence neighbors would be more likely to bind to nucleic acids. Some prediction methods include sequential neighbors of target residues as one of the features for prediction using sliding windows of size $2N + 1$ where N represents nearest neighbors on either side (Walia *et al.*, 2012). Yan and Kurgan (2017) defined nearest neighbors using a sliding window of size 3 (one neighbor on each side); Li *et al.* (2014) used a sliding window of size 5 (2 contiguous residues on each side); Walia *et al.* (2012) used a sliding window of 25 for 12 sequential residues on each side; and Fernandez *et al.* (2011) used varying sizes of sliding windows for 1–8 sequence neighbors.

Structural features

The use of structural features such as solvent accessibility and secondary structure can also assist in the prediction of protein–nucleic acid interactions. Such low resolution structure information can either be derived from a solved protein structure or taken from another sequence-based prediction program, as discussed below.

(1) Solvent accessibility

A protein's binding activities typically occur via their exposed surfaces. Binding residues are more likely to reside in the exposed area, rather than in buried regions. Some methods include predicted solvent accessibility as one of the features used in the prediction (Yan and Kurgan, 2017; Hwang *et al.*, 2007; Tuvshinjargal *et al.*, 2016; Hu *et al.*, 2016). TargetDNA uses SANN (Joo *et al.*, 2012) to predict solvent accessibility using sequence neighborhood and classify each residue into three classes – Buried, intermediate, and exposed residue; DPbind uses information on accessible surface area derived from a DSSP profile (Kabsch and Sander, 1983) in which higher ASA values represent a higher degree of exposure for target residues, and residues below a defined threshold value are annotated as “surface accessible residue”; SRCPred uses ASA information from NACCESS (Hubbard and Thornton, 1993); DRNAPred combines several prediction tools to predict solvent accessibility from sequence using PROFphd (Rost and Sander, 1994), NETASA (Ahmad and Gromiha, 2002), and RVP-net (Ahmad *et al.*, 2003).

(2) Secondary structure

Secondary structure preferences for DNA/RNA-binding sites may also influence the prediction. The DSSP program is able to calculate hydrogen bonds and label predicted secondary structure elements for each residue, including beta sheets, alpha helices, and turns. A PSI-blast based secondary structure prediction method, PSIPRED (McGuffin *et al.*, 2000), is used by DRNAPred to assist the prediction. The program adopts neural networks to predict secondary structure from protein sequence based on the evolutionary conservation profile.

Evaluating Confidence Levels of Predictions

Accuracy, Sensitivity, and Specificity

A number of measures, such as accuracy, specificity, F-measure, MCC, receiving operating characteristics (ROC) curve, and the area under the ROC curve (AUROC) have been used to evaluate the performance of prediction models for making correct classification

of unseen data during testing (Table 3). The raw data generated from predictions are presented in the confusion matrix (Sokolova *et al.*, 2006), which also encode values for true positive (TP), true negative (TN), false positive (FP), and false negative (FN). Values in the confusion matrix are used to calculate the performance measures like accuracy, sensitivity, and specificity, which are some good measures used to evaluate the correctness of the prediction, whether binding residue is correctly identified as such. Accuracy measures the proportion of correctly classified samples against all samples. This is generally not a good measure if the class labels are not equally distributed as in the NA-binding site data. A high accuracy may simply indicate that more residues are labeled in the more populated class (nonbinding). Sensitivity ($TP/(TP + FN)$) measures the true positive rate by calculating true positive samples against the total number of false negative and true positive samples, that is, the proportion of binding residues that are correctly identified. A highly sensitive model for NA-binding sites leads to many residues wrongly labeled to be binding. Specificity, on the other hand, measures the true negative rate by calculating true negative against the total number of true negative and false positive samples that is, the proportion of nonbinding residues that are predicted as such. The F-measure is a harmonic mean of sensitivity and specificity, and MCC can provide a more balanced performance estimate of a prediction model. A comparison of the prediction capability of each tool in Table 1 is provided in Table 3.

Area Under the ROC Curve

Sensitivity and specificity of prediction models can typically be adjusted by a threshold as the predictions are usually on a continuous scale between 0 and 1. To gain a model performance estimate over its full range of predicted scores, the ROC is used. ROC curves can be built between various combinations such as precision recall (P-R curve) or as a plot of true positive rate (sensitivity) represented on the y-axis and true negative rate (1-specificity) on the x-axis, indicating sensitivity/specificity pairs at different threshold values (Sokolova *et al.*, 2006; Fawcett, 2006). AUROC curve can be used to measure accuracy based on a ROC curve. AUROC quantifies to what extent a classifier can make accurate estimates of data labels at various thresholds (Fawcett, 2006).

It may be noted that the prediction scores from different methods may not be directly comparable to each other due to distinct datasets and cross-validation strategies used by individual methods. Therefore, when choosing a method for a new dataset, careful understanding of reported performance levels may be needed.

Illustrative Example(s) or Case Studies

To demonstrate the utility of web servers in identifying DNA- and RNA-binding residues, we have tested a selection of them using individual query sequences derived from protein–nucleic acid complexes – A human transcription factor in complex with double-stranded DNA (PDBID: 5fd3, Chain B) (Marceau *et al.*, 2016) and a human E3 ubiquitin ligase bound to an RNA molecule (PDBID: 5www, Chain A) (Yang *et al.*, 2017). It is clear that most prediction servers can estimate the interface residues in the test protein sequences with high accuracy with small differences in performance.

Prediction of DNA-Binding Residues

The crystal structure of DNA-binding protein Lin54 bound to its DNA promoter (PDBID: 5fd3) was solved with the residues involved in DNA recognition for the cell cycle genes homology region sequence clearly characterized (Marceau *et al.*, 2016). A

Highest value for each column is highlighted in bold.

Fig. 1 Prediction of DNA-binding residues for a human transcription factor sequence. (A) A crystal structure of Lin54 protein containing tesmin domain (Chain B) bound to double-stranded DNA (Chain C and D) (PDBID: 5FD3), with annotated binding residues highlighted in orange color. (B) Predicted binding residues from different prediction tools depicted in the structure. Binding residues are shown in ball and stick representation. (C) Prediction of binding residues from the query sequence containing 134 amino acids. Annotated binding residues is colored in green, predicted binding residue in bold letter, and residue that is correctly predicted as binding is colored in red.

BLAST search against the PDB yielded no other structure with a similar sequence, while searching against the UniProtKB/SwissProt database retrieved similarities to tesmin and cysteine-rich (CXC) domain-containing proteins. Sixteen of the 135 residues in Lin54 are involved in protein–DNA contacts through hydrogen bonds and van der Waals interactions. All tested prediction tools correctly predicted at least 10 residues out of the 16 annotated binding residues (Fig. 1).

Prediction of RNA-Binding Residues

KH domains are known to bind RNA and are important for posttranscriptional activities. The KH-RNA binding interfaces could be observed in the structure of a KH1 domain of human RNA-binding E3 ubiquitin-protein ligase MEX-3C complex with RNA (PDB ID: 5www). Fig. 2 illustrates the annotations derived from the experimental data (Fig. 2(B)) and the comparison between predicted binding residues from different prediction tools (Fig. 2(C–H)). Results indicate lower performance of most prediction methods for RNA-binding residue prediction compared to methods for DNA-binding residue prediction. All methods correctly predicted at least two binding residues from 20 annotated binding residues.

NA-binding residues are usually conserved among homologous proteins. Most prediction methods include annotations from representative protein–nucleic acid complexes in the training sets. Querying for a protein sequence with adequate sequence similarity (sequence identity of more than 30%) to any of the proteins in training datasets would more likely infer binding residues similarly as that of its homologs. Protein sequences used for both case studies however lack such sequence similarities to protein–nucleic acid complexes in the PDB. In both cases, all prediction methods successfully discriminate binding and non-binding residues, regardless of their extent of correctly predicting real binding residues. In such a scenario, the use of PSSM profiles

Fig. 2 Protein-RNA interactions in a KH domain protein predicted by different prediction tools. (A) A comparison of binding residues predicted from the query sequence containing 94 amino acids. Annotated binding residues is colored in green, predicted binding residue in bold letter, and residue that is correctly predicted as binding is colored in red. (B) A crystal structure of KH domain from human E3 ubiquitin ligase, with annotated RNA-binding residues colored in orange. (C–H) Predicted binding residues for RNA sequence annotated from different prediction web servers are shown in the structural context, in order, AaRNA, DRNAPred, PRIdictor, RNABindR, RNABindRPlus, and SRCPred. Binding residues are indicated in ball and stick atom representation.

could improve predictions, as similarly suggested by [Walia et al. \(2012\)](#), since evolutionary information for the query protein is retrieved from a larger number of protein sequences compared to the amount of annotated protein structures. Other than that, the definition of contacts used by individual methods could contribute to the performance variations observed. For example, DP-Bind uses a larger cut-off value of 4.5 Å compared to typical distance cut-off value of 3.5 Å adopted by several methods like AaRNA, DQPred, and DRNAPred, thus creating a larger pool of positive samples.

Discussion and Future Directions

Most of the prediction methods highlighted in this article were intended to determine putative residues important for protein–nucleic acid interaction from protein sequence in the absence of prior annotation for nucleic acid binding or sequence homology. Most prediction methods have been designed with a broad selection of features that include evolutionary conservation, amino acid composition, sequence neighborhood, solvent accessibility, and secondary structure, that have been incorporated into well-established prediction models like neural networks and SVMs. Despite the dependence of these methods on the smaller pool of experimental protein structures, they perform reliable discrimination of binding and nonbinding residues with the assumption that nucleic acid binding interfaces can be similar among proteins of the same group. These methods may potentially be useful to determine novel nucleic acid binding proteins on a proteome level, especially in the case of proteins of unknown function, or proteins for which their ability to bind to nucleic acids has yet to be characterized. Another potential application would be to identify residues for docking simulations to visualize the interactions between proposed binding residues for predicted protein structures or structures believed to be DNA/RNA-binding but solved without the nucleic acid partner present. One perspective that could be of great interest for research in this area is the context dependent functional annotations. In this direction, a breakthrough of sorts has recently appeared in the works of [Ahmad et al. \(2017\)](#) in which they have argued that some DBPs might acquire their

function only in specific cellular environments represented by the gene expression levels of their source gene and also others that are coexpressed. We believe this opens a new direction for functional annotations not only for nucleic acid binding but also for functional annotations in general.

Closing Remarks

The abundance of protein sequences in the sequence repositories, including many genomes that consist of a high number of hypothetical proteins, makes computational sequence level tools useful for assigning functional annotations. Specific tools that are able to predict nucleic acid binding residues will thus be of high utility in cases where nucleic acid binding capacity is hypothesized and/or to identify hypothetical proteins that may have nucleic acid binding capability from the numerous genome sequence datasets now available.

Introduction

Protein-Protein Interactions (PPI)

Eukaryotic cell is a complex collection of physical entities, i.e., biological molecules, which are in a constant flux of association and dissociation reactions. The milieu of cell provides the necessary and sufficient environment for cooperative interactions taking place between biological macromolecules (proteins, RNA, DNA, peptides). Majority of the physical interactions between the cellular components are context-dependent and are highly *specific*. In the case of proteins, the signals for binding events are encoded in their sequences. These signals, or interaction modules, diversify the functions of the proteins to performing activities like catalytic, regulatory, and binding a wide array of ligands. The multifarious functions of proteins in a cell is the reason for the diversity of interactions in a cell (Van Roey *et al.*, 2014).

The eukaryotic cell is composed of many compartments within which a host of reactions and interactions are happening at exceptionally *fast rate* and with high *accuracy* and *fidelity*. The classical approach to understanding interactions is that of a structured protein interacting with a partner. Traditionally, protein-protein interactions (PPIs) are viewed as archetypal interactions between molecules with high affinity and stable domain structures. The assertion that stable, ordered and structured domains are necessary for describing the “interactome” has given way to recent observations that unstructured regions in a protein play a critical role in explaining the cellular events and dynamics of interactions. The regulatory events in a cell tend to opt, perhaps a large fraction, regions of protein without a well-defined stable conformation for the binding sites. These seminal observations have paved the way for a new field of interactome studies known as *Intrinsically Disordered Regions* (IDRs) in proteins (Tompa, 2012). A short stretch of amino acids in protein sequences, in particular IDRs, comprises of binding residues (*functional modules*). These linear interaction sites, or short peptides, have been designated as *short linear motifs* (SLiMs). Hence, the entire array of functions which can be performed by a protein are concentrated in SLiMs. With the availability of a suitable partner which can recognise these sites and bind to them, a sizeable fraction of the interactome can be understood quantitatively (Van Roey *et al.*, 2014; Gouw *et al.*, 2017).

Protein-protein interactions form the basis for many cellular processes. The protein interaction refers to specific physical contact(s) between two or more proteins, forming biologically active protein complex. There are two categories of contacts – *direct* PPI and *indirect* PPI. Indirect PPI are those wherein two interacting proteins may interact forming a complex via intervening partners. Disruption or deregulation of these complex interactions is the main cause of a significant number of diseases. Consequently, there is intense research interest in designing inhibitors that target specific protein-protein interactions. This places intricate protein-protein interactions at the heart of the development for novel protein-based drug leads often referred to as *biologics* (Caputo *et al.*, 2008). The emergence of ‘omic’ technologies, namely genomics, transcriptomics and proteomics, has greatly accelerated our understanding of the protein-protein interaction networks leading to the discovery of a number of proteins and their interactions (Archakov *et al.*, 2003).

Structural Intricacies of PPIs

The number of complex structures has exponentially grown in the Protein Data Bank in recent decades, which partly owes to various Structural Genomics initiatives. With the availability of a large number of structures of protein-protein complexes, the focus in the area has been shifted to understanding the molecular determinants of binding affinity and specificity of complex. The description of the interface in a protein-protein complex serves as a starting point for understanding the chemistry and physics at the interface. When complemented with the physico-chemical description of residues lining the interface, the study becomes quantitative providing deep insight into the interplay of strong and weak interactions during complex formation (Jones and Thornton, 1996; Bravo and Aloy, 2006).

PPI surfaces are relatively shallow and lack features as compared to protein-ligand or drug interactions. These interactions can be viewed as arising out of many cooperative weak interatomic interactions, in contrast to a few strong interactions dictating protein-ligand complex formation (Jones *et al.*, 2000). PPI's are known to be highly regulated and depend on the environment in which they occur. In many cases, the complex formation occurs by post translational modification (like phosphorylation) which promotes recognition by conformational changes in the binding partners. SLiMs are inherently labile and serve as *regulatory motifs* in promoting a large set of protein interactions in surprisingly complex ways (Davey *et al.*, 2015).

Computational Approaches

The existing high throughput experimental approaches such as two-hybrid, chip-based or TAP-MS to map protein interactions suffers from several limitations – Limited data set with high degree of false positives and negatives. X-ray crystallography,

employed to elucidate atomic details of protein interactions, is often not feasible due to crystallization difficulties and complexities of interactions involved in case of membrane domains and multiple interacting partners. Many of the proteins are estimated to possess several interacting partners (Gogl *et al.*, 2013; Meller and Porollo, 2012). The computational methods have the potential to fill-in the gap in this scenario. Computation can be used to predict possible interactions and binding modes, to validate the experimental high-throughput screening data and to analyze the PPI networks from the data repositories (Zahiri *et al.*, 2013). Over 100 such PPI related repositories are available online (Orchard *et al.*, 2012), the prominent among them are – Biological General Repository for Interaction Datasets (BioGRID), Database of Interacting Proteins (DIP), Biomolecular INteraction Network Database (BIND), Molecular Interaction Database (MINT), Human Protein Reference Database (HPRD), Search Tool for the Retrieval of Interacting Genes/Protein (STRING) and IntAct (Miryala *et al.*, 2017).

Protein-Peptide Interactions

Protein-peptide interactions play an important role in many regulatory processes of cell from co-activators to inhibitors and account for almost 40% of the protein-protein interactions. Peptides characteristically interact with specific protein domains such as SH2, SH3, MFC and PDZ domains. Thus development of peptide or peptidomimetic leads is an emerging area in biological therapeutics. Peptides 'as against small molecules' possess specific motifs hence they can mimic protein-binding domains and at the same time they are large enough to serve as competitive inhibitors for disrupting protein-protein interactions. With the objective of developing PPI inhibitors based on peptides or designed peptide derivatives to mimic the binding motif of one of the partners, one usually starts with a sequence similar to or harbouring the *recognition motif* (Stanfield and Wilson, 1995). In solution, the free form of peptides tend to possess a large array of conformations. But, in the presence of an interaction partner there is a drastic reduction in the conformational space sampled by the peptide and the complexation is promoted by the recognition motif with a concomitant lowering of the total entropy of the system (Jackrel *et al.*, 2009; Speltz *et al.*, 2015). It has been commented that PPIs are stabilised in the milieu of strong and weak interactions; but in the case of protein-peptide complexes the hydrogen bonds (particularly backbone-mediated) are pivotal and are key to complex formation (Zvelebil and Thornton, 1993). An attempt to correlate the geometrical parameters of the individual residues in designed peptides, in both free (deposited in Cambridge Structural Database) and bound (as in PDB), has revealed similarities in backbone conformations in the case of aliphatic residues from both the databases. This led to the generation of residue level backbone conformational libraries of peptide residues (canonical) in PDB (Raghavender, 2017).

Peptide-protein interactions have biological significance. They are important signaling components, acting as hormones and neurotransmitters (Brooks *et al.*, 2005; Petsalaki and Russell, 2008). The most famous and important example of a disease involving peptides derived from natural proteins is amyloid beta ($A\beta$), resulting from the hydrolysis of APP protein. Antimicrobial peptides are implied in innate immune system (Ganz, 2003). Further fusogenic peptides have been used as cargo to deliver drugs to target cells (Trabulo *et al.*, 2010). It has been claimed that this subclass of interactions are largely underrepresented in high-throughput experimental techniques used for studying protein-protein interactions (Lensink *et al.*, 2017). The transient nature of the interaction, dictated by the low affinity binding interfaces compounds the existing problems. Computational predictions of peptide binding to interaction partners have been assessed recently (Lensink *et al.*, 2017).

Theoretical Background

Polypeptide Conformation

G. N. Ramachandran is credited with the seminal contribution of describing the conformation of a polypeptide chain in 1960s (Ramachandran and Sasiskharan, 1968; Ramakrishnan, 2001). This resulted in what is now popularly known as **Ramachandran** or (ϕ, ψ) map. The basic idea is to get a 2-dimensional representation of the protein conformation, using backbone dihedral angles (ϕ, ψ). Surprisingly, the map was able to clearly separate regions of regular secondary structural features (α -helices and β -sheets) (Ramachandran *et al.*, 1963). Reverse turns such as α and β -turns, involved in the reversal of the polypeptide chain, could also be completely described using the backbone torsions (Venkatachalam, 1968; Nataraj *et al.*, 1995). The field of designed peptides gained momentum, with the application of conformationally constrained residues which were amenable to chemical synthesis (Balaram, 1992; Toniolo *et al.*, 2001). Aminoisobutyric acid (Aib) is a prototypical achiral amino acid which has been widely examined for the design of helices specifically 3_{10} helices. Proline, an imino acid, is known to occur frequently at the β -turn positions facilitating chain reversals. Hence, both L- and D-enantiomers of proline have been used to design synthetic β -turns as models of β -sheets (Mahalakshmi and Balaram, 2006).

The side chain conformations of residues (rotamers) were also observed to adopt specific conformations. This led to the development of rotamer libraries (Ponder and Richards, 1987) for modelling residue side chain conformations. It was also profitably used in sampling probable conformations in molecular modelling and simulations of proteins and in accurately modelling side chains into electron density maps of structures with not so high resolution (Dunbrack and Karplus, 1993; Dunbrack, 2002; Beglov *et al.*, 2012; Lovell *et al.*, 2000).

Many regulatory events in the eukaryotic cell are transient in nature, meaning they are short-lived as compared to rigid and stable protein complexes. In some such instances, either a short segment of a polypeptide chain or a fragment is involved in interacting with a protein. Initial attempts to elucidate the structural features of protein-peptide interactions revealed that extended

chains (β -strands), β -turns and then by α -helix are the ways in which peptides fold and interact with their partners (Zvelebil and Thornton, 1993). The motifs in these segments were called 'recognition motifs' in the earlier days and are now appropriately called 'SLiMs'. In proteases, like HIV-1 protease, MHC-1, MHC-II, chaperones like PapD and Src homology domains (SH2 & SH3) the recognition motif is usually in an extended chain. Peptide and anti-peptide antibody complexes are frequently seen to bind a peptide with β -turn. Ca^{2+} -dependent calmodulin domain is seen to bind helical peptides. It has become clear that sequence conservation is not necessary for binding to a peptide-binding site, still structures of the bound peptides would have local conserved features (Stein and Aloy, 2008).

Statistical Mechanical Formulation of Molecular Association

A short review of the physio-chemical principles of binding are presented in this section. This should help reader get familiar with the methods used for binding energy estimation and computational docking currently in vogue. We begin with a simplistic formulation of molecular association and disassociation, borrowing from Kilburg and Gallicchio, (2017). Two physical entities A and B can associate by molecular interactions, in a reversible way and at equilibrium can be described by the equations:

The rate of forward and backward reactions are equal at equilibrium, hence *equilibrium constant* for binding K_b can be derived as:

$$K_b = \frac{1}{C^0} \frac{k_{on}}{k_{off}}$$

where C^0 is the standard state concentration set to 1 M. We can now get the standard *binding free energy* ΔG_b^0 , which in principle is a thermodynamic measure of the *binding affinity*, as:

$$\Delta G_b^0 = -k_B T \ln K_b$$

where k_B is Boltzmann's constant. Such a simple formulation will be difficult to reconcile in a biological context, when the interacting species are in a constant flux of interconverting conformations. Hence, the need to resort to statistical mechanical approaches for modelling an "ensemble" of conformations. We skip the derivation and introduce the result of *configurational partition function* of the complex as:

$$Z_{N, A \cdot B} = \int_{\text{bound}} e^{-\beta U(x_A, x_B, \zeta_B, r_s)} dx_A dx_B d\zeta_B dr_s$$

where N is the number of molecules, r_s represents the degrees of freedom of solvent, $U(x)$ represents potential energy of solvent + solute system and ζ_B is any suitable structural parameter (e.g., distance between the center of mass of A and B). The above formulation is the backbone for present-day theoretical models on understanding protein-ligand/protein interactions.

The free energy calculation methods implemented in various programs fall into two distinct approaches. The first approach is based on pathways such as Free Energy Perturbation (FEP), Thermodynamic Integration (TI) and Slow Growth (SG). Such methods are very accurate but computationally intensive. The second set of approaches are less rigorous end-point (two-points) methods such as Linear interaction energy (LIE), Molecular Mechanics-Poisson Boltzmann Surface/Generalized Born Area (MM-PBSA/GBSA) and lambda (λ)-dynamics. They try to balance speed and accuracy to increase throughput to calculate free energy differences (Rathore et al., 2013; Reddy et al., 2014). An end-point method is effective as it ignores the intervening pathway intermediates when evaluating binding free energy, with the description being complete with just free protein, free peptide and protein-peptide states. The binding free energy is estimated in MM-GBSA formulation as:

$$\Delta G_{\text{bind}} = G_{A \cdot B} - G_A - G_B$$

with, $G = \langle E_{\text{bond}} \rangle + \langle E_{\text{ele}} \rangle + \langle E_{\text{vdW}} \rangle + \langle E_{\text{pol}} \rangle + \langle E_{\text{np}} \rangle - TS$

where the contributions come from interactions through covalent bonds (E_{bond}), electrostatic interactions (E_{ele}), van der Waals (E_{vdW}), polar (E_{pol}) and non-polar (E_{np}) forces to solvation free energy. These are typically modelled under implicit solvent representations.

Prediction & Modelling of Protein-Peptides Interactions

Protein-Peptide Docking

The interest towards the development of novel peptide or peptidomimetic has grown substantially in recent times. Peptides are highly flexible and they often interact weakly with their substrate, underlining their importance in signal transduction or regulation which often relies on transient processes. These obstacles make experimental structure determination often non-trivial and calls for complementary computational approaches like docking. Molecular docking is a preliminary step in lead identification and design. Although many well-established methods exist for protein-ligand and protein-protein rigid-body docking, they often fail to yield accurate results in cases that involve receptor flexibility and docking of large, flexible ligands like peptides (Audie and Swanson, 2012; Trellet et al., 2013). Peptides in contrast to proteins are observed to adopt variable conformations. The excursions into

conformational space can be curtailed by designing sequences which have conformationally constrained residues like Pro or non-standard aminoisobutyric acid (Aib) (Mahalakshmi and Balaram, 2006; Raghavender *et al.*, 2010). In a computational investigation involving peptide-protein docking, the peptide conformations are sampled either by running an explicit solvent molecular dynamics (MD) simulation or by a procedure involving implicit solvent simulations using Monte Carlo approaches (Raghavender and Sowdhamini, 2015). The latter is faster and yields results quickly, hence recommended for studies in general. The trajectories in a MD are clustered and low-energy representatives from top clusters are used for docking studies. Due to the lack of prior information on allowed conformations of peptide, it is suggested that all possible conformations be explored for studies.

Docking a peptide to a protein is relatively challenging as it involves considerably more number of degrees of freedom, as opposed to protein-ligand or protein-protein docking. The structure of the receptor protein must be known or one should have structural information of a closely related homolog (Kilburg and Gallicchio, 2016). Present protein-peptide docking procedures fall into two classes, namely:

- (a) *Local Docking* – When there is information available of the binding site on the protein, predicting interactions is more accurately possible (Lavi *et al.*, 2013). In this case, a library of peptides are evaluated for best complex structure. HADDOCK program is suited for this type of investigation. It even allows the user to guide the docking by incorporating the biochemical and biophysical data into the docking protocol (Spiliotopoulos *et al.*, 2016). GalaxyPepDock is web based service which employs similarity-based docking. It builds model peptide conformations by identifying templates from the database of experimentally determined structures followed by energy-based optimization that allows for structural flexibility (Lee *et al.*, 2015). MedusaDock is another program which can effectively be used for induced-fit docking procedures (Ding and Dokholyan, 2013). The best pose selection in any of the above programs follows the authors own approach, hence there is a need to look at each pose carefully before proceeding further with analysis. Glide peptide docking module in Bioluminate (Schrödinger, 2017) systematically improve pose prediction accuracy of flexible peptides by enhancing characteristic Glide sampling using a series of hierarchical filters to search for accurate binding mode. The scoring of the poses is improved by post-processing with implicit solvation based MM-GBSA calculations (Tubert-Brohman *et al.*, 2013). Glide peptide docking method is accurate and several times faster than other programs. Rosetta FlexPepDock is a robust protocol for Protein-peptide docking (Raveh *et al.*, 2010) which tries to optimize the peptide backbone and rigid body orientation, using the Monte-Carlo with Minimization approach. Dyna method is new approach for docking peptides into flexible receptors. It follows a two step procedure: the Protein-Peptide conformational space is scanned first to approximately identify ligand poses followed by the pose-refinement by a new molecular dynamics-based method, optimized potential molecular dynamics (OPMD) using soft-core potentials for the protein-peptide interactions (Antes, 2010).
- (b) *Global docking* – When there is little or no information available on the binding site, it needs to be searched for on protein surface. Such methods have limited accuracy for predicting the complex structures. However, there are recent examples of successful predictions of such methods (Yan *et al.*, 2016; Petsalaki *et al.*, 2009). In this scenario, one performs a docking with an ensemble of peptide conformations onto the surface of the target protein. Typically, one can complement it with some biochemical information on the plausibility of the binding site to be correlated with some interaction. Generally, one proceeds in a two-tiered way involving coarse-grained modelling of the receptor for filtering binding sites followed by atomic resolution docking and refinement. Programs like CABS-dock and PepATTRACT have been used recently in such studies (Blaszczuk *et al.*, 2016; De Vries *et al.*, 2017).

Predicting Hot-Spot Residues: Residue Scanning

The prediction of energetically important amino acid residues at the interface of protein-protein complexes is a step forward in biologics design. Such *hot-spot* residues (i.e., residues that significantly destabilize the PPI when mutated to Ala or specific residues possessing different chemical and structural character) have been investigated experimentally as well as computationally. Experimental site-directed mutagenesis is a powerful method for delineating important residues and key interactions at the protein-protein interfaces. A number of reports describe computational mutagenesis involving calculation of the effect of mutations on the binding free energy of protein-protein complexes using empirical energy models such as Robetta & FoldX (Kortemme *et al.*, 2004; Schymkowitz *et al.*, 2005). Other sophisticated methods of binding free energy calculation upon alanine mutation using implicit solvation models such as MM-PBSA/GBSA and Thermodynamic Integration have been proposed (Martins *et al.*, 2013; Beard *et al.*, 2013) even though they are computationally much more expensive. The MM-GBSA approach implemented in Bioluminate Residue scanning module (Schrödinger, 2017) employs the OPLS force field and the VSGB2.0 solvent model to calculate binding free energy differences between wild type and mutants. The individual or multiple residues are mutated followed by rotamer search algorithms implemented in Prime (Schrödinger, 2017). In an experimental data set comprising of 418 single residue mutations in 21 targets, the MM-GBSA based method has been demonstrated to perform well at picking hot-spots, and mutations within an accuracy of 1 kcal/mol (Beard *et al.*, 2013).

Case Studies

We present a few of the research investigations here which cover in part of the above concepts.

- (i) Nuclear receptor (NR) box II peptide, with LxxLL motif (x is any amino acid), binds to oestrogen receptor α . One can see that the peptide forms an amphipathic α -helix and is lodged in a complementary groove on the receptor surface (Shiau *et al.*, 1998).

- (ii) PDZ domains which are protein interaction modules involved in signaling networks, bind the C-terminal regions of partners by adding a β -strand. This is known as β -augmentation (Remaut and Waksman, 2006).
- (iii) SH3, WW and EVH1 domains, bind to linear motifs rich in proline residues and adopting polyproline II helix structures (Zarrinpar et al., 2003).
- (iv) SH2, PTB and 14-3-3 domains are known to bind sites involved in post-translational modifications (Rittinger et al., 1999).
- (v) MDM2-p53 interaction is known to be lethal. Mouse Double minute 2 (MDM2) binds to a short helix on p53. This interaction was mimicked by *cis*-imidazoline analogs, called Nutlins, which could completely inhibit the complex formation (Vassilev et al., 2004).

Discussion

We elaborate on few of the important investigations discussed above in the following section.

- (i) *NR box II peptide + oestrogen receptor α (ER α)*. The transcription factor ER α is involved in the regulation of differentiation and maintenance of neural, skeletal, cardiovascular and reproductive tissues. Treatment of breast cancer, osteoporosis and cardiovascular disease employs compounds which modulate ER α activity. ER α binds a variety of ligands, and all the ligands bind at the C-terminus. In the structure of NR box II peptide bound to ER α , it can be seen that the peptide is helical, with approximately 1000 Å² hydrophobic surface area buried at the interface. The ligand binding domain (LBD) interacts primarily with the side chains of the peptide residues Ile-689, and Leu-690, Leu-693 and Leu-694. This interactions was found to be very potent and involving mostly non-polar interactions (van der Waals). Terminal capping interactions stabilize the lodged peptide, the γ -carboxylate of Glu-542 hydrogen bonds to the N-terminus of the peptide and Lys-362 (ϵ -amino group) forms hydrogen bonds with the C-terminus of the peptide helix (PDB code: 3ERD).

Fig. 1 Bivariate kernel density estimates (kde) of backbone torsion angles (ϕ , ψ) of peptide residues bound to protein partners in PDB. High resolution crystal structures, better than 1.5 Å, were used for the analysis. Only canonical residues have been investigated, with a view of utility in chemical synthesis of analogs. Cyclic peptides were excluded from the study.

Fig. 2 Ramachandran Plot of the proline residues in CSD. The regions corresponding to helical (α_R -right-handed α_L -left-handed) and extended strands are marked in red circles. Cyclic peptides are also included in this plot for completeness, and they tend to be clustered at (0, 0). Reproduced from the Doctoral Thesis of Dr. U.S. Raghavender.

- (ii) *C-terminus pentapeptide from post synaptic protein CRIPT + Synaptic protein PSD-95*. PDZ domains are known to be involved in important metabolic pathways. In the structure of synaptic protein PSD-95 in complex with a peptide derived from C-terminus of CRIPT, one observes that the peptide adopts a β -strand conformation and binds to the edge of the β -sheet from PSD-95. The protein-peptide complex formation in this case is augmented by the main chain interactions. The affinity of the interaction is directed by peptide backbone interactions leaving a wide scope for specificity, promoting the binding of shorter motifs at the binding site (PDB code: 1BE9).
- (iii) *MDM2-Nutlin-2 complex*. MDM2 is a ubiquitin protein ligase and is known to bind to a short amphipathic α -helix on the p53 tumor suppressor and modulate its transcriptional activity and stability. The functions of p53 are impaired upon overexpression of MDM2 in human tumours. Hence, inhibition of MDM2-p53 interaction is a way forward for cancer therapy. The small molecule inhibitor, Nutlin-2, mimics the interactions of the p53 peptide to a high degree, with one bromophenyl moiety sitting deeply in the Trp pocket, the other bromophenyl group occupying the Leu pocket, and the ethyl ether side chain directed toward the Phe pocket. The imidazoline scaffold serves as a functional replacement of helical backbone of the peptide and is able to direct the projection of three groups into the pockets normally occupied by Phe. This is one of the very first studies in identifying small molecule compounds which involved disrupting a pathological protein-peptide interaction (PDB code: 1RV1).

Future Directions

First principle studies on protein-peptide interaction are presently out of reach from the perspective of both methods and the software programs implementing the theoretical approaches. A great step forward would be to comprehensively catalog, characterize, and associate Protein-peptide interactions with disease and other phenotypes. There is a good scope for development in all the areas of mechanistic description of protein-peptide interactions. In particular, sound theoretical approaches to accurately model the interaction incorporating both the chemical and physical information can be explored. Peptide design, protein-peptide docking and refinement of docked complexes have already been addressed computationally using many different approaches; still the search is ON for the best method which would be able to predict the correct protein-peptide interaction accounting for all the

variabilities in peptide conformations. Computers with ever increasing and improving processing speeds and hardwares, are making these studies feasible in desktop workstations. With the surge of GPUs, there is a good scientific reason to traverse to the new avenues exploiting the new computer architectures for these studies.

Closing Remarks

The prevalence of peptide-protein interactions in a cell has been established by many complementary physical, chemical and biochemical experiments. It is very clear that these are very abundant in a cell and are primarily involved in cellular regulation, thus offering enormous scope for protein therapeutics. The existing experimental approaches to characterize PPI have high rates of false positives and computational methods serve an important role to predict and derive a mechanistic picture of these interactions. The limited accuracy of predictive methods calls for improving the existing computational methodologies. Additional and complementary physical and computational approaches can help remove ambiguity in predicting a true positive interaction, which can subsequently be validated using experimental techniques. The description of the entire interactome warrants accurate characterization and prediction of this important subclass of PPIs (Figs. 1, 2, 3).

Biographical Sketch

Dr. U.S. Raghavender did his Masters in Physics (specialization in Condensed Matter Physics) from the University of Hyderabad and obtained his PhD in Biocrystallography of Designed Peptides from the Indian Institute of Science (IISc, Bangalore) in 2010. He did his post-doctoral studies in Stanford Research International – Center for Advanced Drug Research (USA), National Center for Biological Sciences (NCBS-TIFR, Bangalore, India) and The Hebrew University of Jerusalem (Israel) in the area of computational studies involving protein-peptide interactions. He has expertise in peptide design, conformational analysis and computational studies of peptide mediated interactions. His research interests include applying computational approaches to studying transient protein-protein and protein-peptide interactions. His interests also span in studying genomes and transcriptomes of medicinally important plants. He is a recipient of award of Young Scientist Scheme of Science and Engineering Research Board (Department of Science & Technology, Government of India).

Dr. R.S. Rathore obtained M. Phil. In 1991 from Devi Ahilya University, Indore and PhD in 1999 from Indian Institute of Science, Bangalore, India, in Structural Biology in the area of X-ray crystallography and peptide *de novo* design. He further pursued postdoctoral work on protein crystallography and peptide design at the University of Texas Medical Branch at Galveston, USA. He is currently working as a Professor in the School of Earth, Biological and Environmental Sciences, Central University of South Bihar, Gaya, India. Rathore earlier worked in University of Hyderabad, India and Schrödinger Inc. (USA). His main interests are protein modelling and design and Free Energy Perturbation method for lead optimizations. He has published 95 articles in peer reviewed journals.

Homologous Protein Detection

Xuefeng Cui and Yaosen Min, Tsinghua University, Beijing, China

Introduction

Proteins carry a wide variety of functions within organisms. For example, antibody proteins can act as virus fighters to neutralize the target function causing a disease; enzyme proteins can act as catalysis to accelerate a chemical reaction by lowering its activation energy; hemoglobin proteins can transport oxygen via arterial blood; fibrous proteins can make up structural components, such as skin, hair, and nails. This is why it is very important to study how proteins function in organisms.

If we could understand how proteins function, we should be able to modify existing proteins or even to design new proteins. The newly designed proteins could help us to fight against cold virus or even Ebola virus, to further accelerate or even to slow down a chemical reaction within organisms. The ultimate goal of such protein designs is to benefit human lives, such as no one would get cold any more, or everyone could drink sea water directly. Unfortunately, we still understand very little about how proteins function, and biologists are still trying hard to study how proteins function in organisms.

It is widely accepted that protein functions are determined by protein structures (Crick, 1958). If we could find proteins with similar structures and similar functions, one could focus on the similarities as hints. Such hints suggest that the similar part of the complete protein structure tends to be the functioning part of the protein. This approach should significantly reduce the search space and hence speed up the study on protein functions. Initially, this work was done manually by expert. However, since biologists have experimentally determined more than 100,000 protein structures (Berman *et al.*, 2000), it is extremely labor extensive to exam the similarities between each pair of proteins manually.

This motivates the computational problem of homologous protein detection that automatically find proteins sharing a common ancestor during the course of evolution. Such homologous proteins tend to share conserved protein sequences, structures and functions. Thus, these proteins should be ideal cases for biologists to study how proteins function. Moreover, computers are much cheaper and faster comparing to human labors. Therefore, the homologous protein detection becomes an irreplaceable step towards understanding how proteins function.

Background

Formally, a protein complex consists of one or more chains of amino acids. Each chain is also called a polypeptide because the amino acids are connected by peptide bonds. For sake of simplicity, a protein in this article is referred to a single polypeptide. Then, a protein can be represented by a sequence of amino acids connected by peptide bonds, or a number of atoms in three-dimensional space connected by peptide or covalent bonds. Detailed explanations of related terminologies are provided as followings.

Amino acid: Amino acids are small organic molecules containing amine ($-NH_2$) and carboxyl ($-COOH$) functional groups, along with a side chain (i.e., the R group), which is used to identify the amino acid as shown in Fig. 1. Moreover, the carbon atom connected to the side chain is referred as the C_α atom, which is marked as a star in the figure. In total, there are 20 kinds of common amino acids identified by 20 kinds of side chains, and each kind of amino acids can be represented by a single character.

Polypeptide: Two or more amino acids form a polypeptide via dehydration reactions, and the polypeptide could be identified by its peptide bonds, which are amide groups as shown in Fig. 2. Each polypeptide has an N-terminus (i.e., the amine end) and a C-terminus (i.e., the carboxyl end). Usually, the amino acids that have been incorporated into polypeptides are also called “residues”, and the residues are counted from the N-terminus to the C-terminus.

Primary structure: A protein is a polypeptide containing more than 50 residues. Recall that a polypeptide is a chain of residues, and each residue can be represented by a single character. Then, the primary structure or simply the sequence of a protein can be represented by a sequence of characters, where each character represents the type of the corresponding residue.

Secondary structure: The secondary structure of a protein indicates local structure patterns formed by hydrogen bonds between residues. The two main types of protein secondary structures are α -helices and β -sheets. The cartoon in Fig. 3 (drawn using PyMOL, Delano, 2002) has been widely used to show the trace of residues forming an α -helix on the left and a β -sheet on the right. It can be seen that the α -helix has a right-handed helix pattern, and the β -sheet has a sheet pattern formed by parallel or anti-parallel β -strands.

Tertiary structure: The tertiary structure or simply the structure of a protein refers to the three-dimensional structure of the polypeptide. Fig. 4 shows an example protein containing mainly α -helices that are connected by loop regions. A simplified representation of a protein structure consists of the three-dimensional coordinates of representative atoms. Typically, the C_α atom can be used as the representative atom for each residue because it approximately defines the three-dimensional location of the residue. Hence, the protein structure can be represented by a sequence of C_α coordinates in three-dimensional space.

Fig. 1 An amino acid containing a C_α atom (star), an amine group ($-NH_2$), a carboxyl group ($-COOH$) and a side chain (R).

Fig. 2 A polypeptide with five residues.

Fig. 3 Secondary structures of proteins: An α -helix (left) and a β -sheet (right).

Quaternary structure: The quaternary structure of a protein complex refers to the overall three-dimensional structure of a protein complex consisting of two or more polypeptide molecules and possibly other molecules, such as ligand or RNA molecules. Since all the molecules are interacting with each other, they are called a protein complex. [Fig. 5](#) shows one example quaternary structure, but quaternary structures are beyond the scope of this article.

Homologous Protein Detection

In biology, homologous proteins are the ones sharing a common ancestor. Since we do not know the exact evolution histories of proteins, homologous proteins are computationally defined as proteins sharing significant similarities. For example, assuming that each residue is randomly selected from the 20 kinds of residues, the probability to see two protein sequences sharing N common residues is 20^{-N} . If N is a big number, such as 100, the probability becomes very small (i.e., $20^{-100} = 7.9 \times 10^{-131}$). Thus, such similarities are highly unlikely to happen by chance, and such observations should be strong evidences for homologous proteins. Therefore, such proteins are presumed to be homologous proteins in computational biology.

There are mainly two kinds of evidences commonly used to find homologous proteins: protein sequences and protein structures. The computational problem to find sequence similarities between a pair of sequences is called the sequence alignment problem, which is actually a string matching problem. Given two strings, the goal is to find character matchings between the two strings that maximizes a scoring function. Typically, a match could have a score of $+1$, a mismatch could have a score of -1 , and an in-del (i.e., an insertion or a deletion) could also have a score of -1 . Then, it is possible to use a dynamic programming algorithm ([Needleman and Wunsch, 1970](#); [Smith and Waterman, 1981](#)) to find the optimal solution that maximizes the scoring function.

Fig. 4 The tertiary structure of a protein.

Fig. 5 The quaternary structure of a protein complex: A single chain (left) making up a complex (right).

The problem described above is a simple version of the protein sequence alignment problem (Henikoff and Henikoff, 1992; Altschul *et al.*, 1990; Ma *et al.*, 2002; Remmert *et al.*, 2012). In practice, a biologist might be interested in different things, and hence there are different algorithms designed for different requirements: finding global similarities or finding local similarities, targeting high accuracy or targeting high speed, and so on. Moreover, different scoring functions have also been designed: assuming all aligned residue pairs are independent, assuming the aligned residues pairs are position-specific, assuming the aligned residues pairs are pairwise dependent, and so on.

Finding homologous proteins with structure similarities is much more complicated but more meaningful. Recall that protein functions are determined by protein structures. Sequence similarities work well in practice because proteins with highly similar sequences tend to have highly similar structures (e.g., Fig. 6). Moreover, it is computationally much faster to find sequence similarities than structure similarities. However, there are many homologous proteins sharing little sequence similarities but still sharing high structure similarities (e.g., Fig. 7). Such homologous proteins are called remote homologous proteins because they are conceptually remote as suggested by sequence similarities.

The computational problem to find structure similarities between a pair of protein structures is called the structure alignment problem (Kolodny *et al.*, 2005; Hasegawa and Holm, 2009). It can be divided into two sub-problems: the residue matching problem and the superposition problem. The residue matching problem is similar to the sequence alignment problem. The only difference is on the scoring function, which is now based on the distances between the aligned residue pairs in the three-dimensional space. The superposition problem is to find a rotation and a translation to rigidly transform one protein structure to the other one so that the aligned residue pairs are located closely each other.

The protein structure alignment problem is computationally expensive because its two sub-problems have a chicken-egg relationship: solving the residue matching problem requires the structures to be rigidly transformed first, while solving the superposition problem requires the residues to be aligned first. If we know the answer of one problem, it is computationally efficient (i.e., there exists algorithms running in polynomial time) to solve the other problem. However, if we would like to solve both problems at the same time, the problem becomes NP-hard (Goldman *et al.*, 1999; Li and Ng, 2011). Therefore, many heuristic algorithms are designed based on the idea of sampling local similarities first and then producing global similarities by

enlarging or combining local similarities (Shindyalov and Bourne, 1998; Krissinel and Henrick, 2004; Zhang and Skolnick, 2005; Cui *et al.*, 2013). Unfortunately, such heuristic algorithms can only find local optimal solutions.

Like the sequence alignment problem, different structure alignment algorithms have been designed to satisfy different interests of biologists: using global structures or focusing on interaction interfaces, targeting high accuracy or targeting high speed, using only structure information or fusing other available information (e.g., secondary structure information), and so on. Some algorithms also try to avoid solving the superposition problem, and to solve the residue matching problem directly (Holm and Sander, 1993; Holm and Rosenström, 2010). The main idea here is to use pairwise distances instead of three-dimensional coordinates to represent protein structures. The trick of such algorithms is that the pairwise distances do not change after any rigid transformations. However, the residue matching problem for the new presentation is still NP-hard, and simulated annealing algorithms have been used to solve the problem with local optimal solutions.

There is a highly related problem called the protein threading problem (Roy *et al.*, 2010; Källberg *et al.*, 2012; Söding *et al.*, 2005), which tries to find similarities between a protein without structure information (i.e., with primarily sequence information) and a protein with structure information. The motivation is the fact that there are significantly more proteins with known sequences than proteins with known structures. The main challenge here is how to compare the cross-modal information. The classical approach is transferring the sequence and the structure space into other spaces, such as the secondary structure space, the

solvent accessibility space, and so on. Then, similarities can be found in the sequence and the transformed spaces. Recently, cross-modal learning algorithms (Lhota *et al.*, 2015; Cui *et al.*, 2016) have also been used to avoid such space transformations, and to solve the problem in two or more modals directly with improved accuracy.

Other than protein sequences and protein structures, many evidences have also been used to find homologous proteins. For example, if two proteins interact with the same group of proteins, they could also be presumed to be homologous proteins. However, such evidences carry less information comparing to the structure evidences because finding correlations between structures and functions is the key to understand how proteins function. Based on such protein-structure correlations, biologists can first hypothesize how proteins function, and then design biology experiments or molecular dynamic simulations to validate the hypothesis (Wüthrich and Wagner, 1978; Bennett *et al.*, 1984). Although protein-protein interaction evidences cannot directly help to understand how proteins function, they could perform better than sequence or structure information for applications, such as the protein function prediction (Radivojac *et al.*, 2013).

Application: Drug Repositioning

Drug design is both a time consuming and expensive task. The complete drug design process contains several stages: the early drug discovery stage, the pre-clinical research stage, the three clinical trial stages, the application stage and the post-approval study stage. Each stage could take between two and eight years, and the total time required for the complete process is typically between 15 and 25 years. Unfortunately, many patients cannot live that long waiting for the drug release. On the other hand, many patients cannot afford new drugs because of the high drug price due to the high cost of drug design. Taking America in 2013 for example, the total amount of money spent on drug design is approximately 50 billion US dollars, while there are only approximately 25 drugs released. On average, the cost to design a new drug is approximately two billion US dollars. Therefore, it is highly desirable to save both time and money to design new drugs.

It is difficult to save time and the money to design new drugs for several reasons. One reason for the long time is that finding a new drug candidate in the early drug discovery stage is labor intensive. This is actually where computers could help; thus, many algorithms have been designed for this purpose. Even with the help of modern computers and classical algorithms, finding a new drug candidate is still very difficult because of the infinite number of possible candidates. One reason for the high cost is that more than 90% of the drug candidates will fail the clinical stages. For example, it is very difficult to predict if a drug candidate has toxicities or other unacceptable side effects. Such issues can only be discovered by biology experiments or even clinical trials. Since most drug candidates failed the clinical trials, all the money spend in earlier stages will not produce any outcome.

Recently, a key observation opens a new door to solve the drug design problem. Traditionally, each drug was proposed to treat only one disease. However, recent experiments show that each drug could interact with six different proteins, on average, that exists in the human organism. Other than the target protein that is responsible for the disease, most interacting proteins are responsible for side effects or even toxicities. However, there are happy accidents such that the released drug could also interact with a protein that is responsible for another disease. That means, there exists drugs proposing to treat one disease could also treat another disease.

Finding such unknown relationships between drugs and diseases could significantly save time for drug design. Recall that finding a new drug candidate is difficult because of the infinite search space. Scanning the complete drug database for drug candidates reduces the infinite search space to a much smaller and finite search space. As a result, it could take only a couple of days for modern computers to finish the task. Once succeeded, it could save more than eight years of time by skipping the early drug discovery stage, the pre-clinical research stage, and the first clinical stage of drug design. Consequently, this could reduce the drug design time by a factor of approximately two.

Finding such unknown relationships between drugs and diseases could also save a lot of money for drug design. Recall that the high cost of drug design is mainly due to the high failure rate. However, new drug candidates are selected from the released drugs that has previously passed all clinical trials. Then, such drug candidates are highly likely to pass the clinical trials again. Previously, the main reason of the failure rate is because of the unacceptable side effects and toxicities. Now, the main reason becomes the advances in the clinical trials. This should instantly change the high failure rate to a high success rate. As a result, this could reduce the money required to design a new drug by a factor of at least ten.

In computational biology, the problem of finding such unknown relationships between drugs and diseases is called the drug repositioning problem (Ashburn and Thor, 2004; Chong and Sullivan, 2007). One approach to solve the problem is to apply structure alignment algorithms on the interaction interface structures (Gao and Skolnick, 2010; Cui *et al.*, 2015a,b; Naveed *et al.*, 2015). The idea is that if two interaction interfaces have highly similar structures, they tend to interact with the same group of drugs. For example, two novel target proteins, the peroxisome proliferator-activated receptor gamma and the oncogene B-cell lymphoma 2, have been discovered using this method. Both target proteins were first computationally predicted by structure alignment methods, and then experimentally verified by biological methods.

The drug repositioning approach is becoming more and more important for pharmaceutical companies as more and more drugs have been proposed using the approach. For example, Requip was initially proposed as a treatment of Parkinsonian, and then repositioned as a treatment of Restless Legs Syndrome; gabapentin was initially designed as an anti-epileptics drug, and then repositioned as a neuropathic pain reliever drug; and so on. Therefore, the success of drug repositioning has saved not only decades of time, but also tens of billions of US dollars for pharmaceutical companies. In the coming years, more computational drug repositioning methods will be proposed by computational biologists, and more repositioned drugs will be released by pharmaceutical companies. Consequently, more patients would be benefited from these repositioned drugs.

Application: Structure Determination and Prediction

Since protein structures are irreplaceable for understanding protein functions, several experimental methods have been designed to determine protein structures. Due to the importance of the problem, three Nobel Prizes have been awarded to protein structure determination methods: X-ray crystallography (Garman and Schneider, 1997), nuclear magnetic resonance (NMR) spectroscopy (Wüthrich, 1990) and cryo-electron microscopy (cryo-EM, Kühlbrandt, 2014; Callaway, 2015) in 1915, 1991 and 2017, respectively.

Current protein structure determination methods share a common high-level procedure. First, protein samples are purified and pre-processed. Then, experimental data are measured using the protein structure determination device. For example, an X-ray crystallography device produces scatter plots of the differentiation effects caused by the protein crystal; an NMR spectroscopy

device produces atom-atom distances between close atoms of the protein structure; and a cryo-EM device produces two-dimensional projections of the three-dimensional protein structures. Finally, these experimental data are analyzed to build protein structure models (i.e., the three-dimensional coordinates of all atoms). The last step is done computationally as a data science problem to find protein structure models that are consistent with the observed experimental data.

Ideally, the experimental data contain small errors and the true protein structure model could be easily unveiled. For example, the scatter plots of X-ray crystallography could be used to reconstruct the electron density map containing all atoms of the protein structure. Such an electron density map could be imagined as a three-dimensional photo of the protein structure, where each atom is represented by a ball and each bond is represented by two overlapping balls. Thus, the protein structure model can be computed from the electron density map. Unfortunately, only a very small number of X-ray crystallography experiments have produced such ideal-quality protein structure models.

Generally, experimental data are not sufficient to build protein structure models directly; thus, additional knowledge-bases have to be used. For example, the bond lengths and the bond angles (between two connected bonds sharing a common atom) should have very small variances (Evans, 2007; Jaskolski *et al.*, 2007). Moreover, the bond torsion angles (between two bond surfaces defined by three connected bonds) should obey a specific distribution (Laskowski *et al.*, 1993; Davis *et al.*, 2007). Such constraint and restraint knowledge can be used to reduce the model search space to protein-like structures. The goal is to build a protein structure model that is consistent with both the knowledge-bases and the experimental data. Approximately, 30% of the X-ray crystallography experiments have produced such high-quality protein structure models (Berman *et al.*, 2000).

For the remaining 70% of the X-ray crystallography experiments, homology modelling methods are used to produce the protein structure model. The main problem here is the quality of the experimental data. Actually, homology modelling methods are even more popular when processing cryo-EM data because of their low data quality (Lawson *et al.*, 2010). The idea of homology modelling methods is first identifying a homologous protein with a similar structure, and then refining the homologous structure to better fit the experimental data. Here, the key problem is to find a good homologous protein as the template structure. This can be done by employing sequence alignment algorithms, threading algorithms and recently cross-modal learning algorithms. These methods are highly related to the protein structure prediction methods described in the following two paragraphs.

Currently, multiple protein structure determination methods are frequently used because each method has its own advantages and limitations. Specifically, an X-ray crystallography device is able to produce protein structures with the highest qualities but it requires the proteins to be crystalized first, which is difficult or even impossible for large proteins; an NMR spectroscopy device is able to produce dynamic protein structures but the produced structure might contain a lot of errors; a cryo-EM device is able to produce large protein complex structures but the qualities are limited. Moreover, neither method is capable of experimentally determining all protein structures.

This motivates the protein structure prediction problem, and homology modelling methods again play key roles to solve the problem (Moult *et al.*, 2017; Haas *et al.*, 2017). Specifically, given the sequence of a target protein and the knowledge-base of all known protein structures, the first step is to identify a homologous protein structure from the knowledge-base. Then, the homologous protein structure is used as a template to initialize a decoy structure. The final predicted structure is produced by refining the decoy structure to optimize a potential energy function. A typical potential energy function involves the bond forces, the electrostatic forces and the van der Waals forces, and it is usually time consuming to evaluate (Brooks *et al.*, 1983; Webb and Sali, 2014). Since homology modelling methods significantly reduce the model search space, the number of times to evaluate the potential energy function is significantly reduced (Roy *et al.*, 2010; Källberg *et al.*, 2012; Söding *et al.*, 2005; Cui *et al.*, 2016). Therefore, homology modelling methods usually perform much faster than Ab Initio methods.

Protein structure determination and prediction problems are among the most wanted solutions in biology, and breakthrough technologies have been developed recently to advance the existing solutions. The central dogma of molecular biology tells us that the RNA polymerase is responsible for the transcription function, the spliceosome is responsible for the splicing function, and the ribosome is responsible for the translation function. Two Nobel Prizes have been awarded to solving the RNA polymerase structure and the ribosome structure in 2006 and 2009, respectively. Since 2012, cryo-EM opens a new gate to determine protein structures, and it has been used to solve many key protein structures, including the polymerase structure in 2015, playing key functions in organisms. In the future, computational methods will play more and more important roles in structure determination technologies and structure biology.

Discussions

In this article, we have covered the fundamentals of finding homologous proteins and its applications. It has been shown that it is important to find homologous proteins because they carry key information on studying how proteins function. Indeed, homologous protein detection is highly likely the first step in almost all protein function researches. Therefore, finding homologous proteins is a fundamental problem in protein bioinformatics.

Although many researchers have been working on this topic, there are still a lot of open problems waiting to be solved. For example, existing methods work well for homologous proteins within the same family or the same super-family. The main reason is that such homologous proteins tend to have global structure similarities, and this reduces the difficulty of the problem. However, for homologous proteins within the same fold, conserved high-level structure patterns can still be observed by human experts. Due to the lack of global structure similarities, it is more challenging for computational methods to distinguish true

homologous proteins from the false ones. Thus, different computational methods tend to have different results, and the results might disagree with each other. Actually, there is no theoretical guarantee on finding such homologous proteins for any computational methods; thus, homologous protein detection in the fold level remains open.

This article also shows that computational methods are playing critical roles in protein structural biology. Actually, this is not only true in protein structural biology, but also true in life science. Indeed, recent advances in life science is driven by mathematical, statistical and computational methods. It is not difficult to see that the situation will remain the same in the future, and more interdisciplinary talents are needed to accomplish our goals.

Introduction

AIDS and HIV

Acquired immunodeficiency syndrome (AIDS) spread by the human immunodeficiency virus (HIV) has become an epidemic worldwide (Sanou *et al.*, 2012). In 2016, it is assessed that about 36.7 million people were living with HIV, 19.5 million people were living with HIV on antiretroviral therapy, and a huge 1.8 million people were newly infected with HIV, and the infection is spreading at a shocking proportion. UNAIDS projections indicate that an additional 50 million people will be freshly infected in the coming decade, if the world doesn't get through to develop a potent therapy/medication (drugs or vaccine). However, remarkable progress against AIDS over the past 15 years has stimulated a global commitment to end the epidemic by 2030 (see "Relevant Websites section").

The lethal virus attacks the human immune system targeting the helper T-cells (specifically CD4⁺ T cells), macrophages, and dendritic cells (Cunningham *et al.*, 2010) reducing the human immunity (Hatzioannou and Evans, 2012). Regardless of vigorous public health efforts and laborious research efforts, AIDS remains a fatal syndrome. Nevertheless, antiretroviral therapy has given a chance to tackle AIDS in part, but due to the clever HIV the goal for complete destruction of the epidemic remains distant. Mutation-induced drug resistance has abolished the clinical effectiveness of most of the FDA-approved drugs administered. So, there is a great demand for developing and designing a potent and less vulnerable drug for antiretroviral therapy. As shown in Fig. 1, HIV is a globular enveloped retrovirus, enclosing dual copies of single-stranded, positive-sense RNA (Ganser-Pomillos *et al.*, 2012). HIV infection starts with the attachment of the matured virus to the host cells containing CD4⁺ receptors and coreceptors CCR5 or CXCR4 with their envelope glycoproteins gp41 and gp120 (Tran *et al.*, 2012). Upon attachment, the host cell membrane and the viral envelope dissolves and the inner genomic content (RNAs) of the virus enters to the host cell. The RNA is then reversibly transcribes to viral DNA by the reverse transcriptase (Le Grice, 2012), which is followed by transcription, translation to form large polypeptide chain (Gag and Gag-pol). The large polypeptide chain is eventually cleaved by the proteolytic events by HIV-pr to form small structural and functional proteins of the virus. Subsequently, with the process of budding and assembly (Bukrinskaya, 2007), the synthesized proteins and part of host cellular membrane form the new virions for next phase of infections to the new CD4⁺ cells.

HIV-1-Protease (HIV-Pr)

HIV-pr is an essential enzyme of HIV replication, and is a vital target for drug design strategies to fight AIDS. It cleaves the Gag and Gag-Pol polypeptides to generate the mature infectious virions capable of CD4⁺ cells infections (Fun *et al.*, 2012). Deactivating the enzyme's function creates immature virions without having the infectious supremacy. Keeping that in mind, several drugs have

Fig. 1 A schematic structure of a Human Immunodeficiency Virus type 1(HIV-1). Credit: National Institute of Health (NIH).

Fig. 2 2D structures of HIV-1 protease inhibitors that are approved by FDA to treat AIDS. Adapted from a research article Arodola, O.A., Soliman, M.E.S., 2015. "Could the FDA-approved anti-HIV PR inhibitors be promising anticancer agents? An answer from enhanced docking approach and molecular dynamics analyses." *Drug Design, Development and Therapy* 9, 6055–6065.

been designed, developed, and finally approved by FDA against AIDS. To date, at least nine FDA-approved protease inhibitors have been rolled out (**Fig. 2**), but none of them is effective after prolonged treatment time due to mutation-assisted drug resistance.

HIV-pr is a homodimeric aspartyl protease with C2 symmetric in the free form (Brik and Wong, 2003), containing 99 amino acids in both of its chain-A and B. HIV-pr residues are numbered as 1–99 for chain A and 1'–99' for chain B. Flap (residues 43–58 and 43'–58'), flap elbow (residues 35–42 and 35'–42'), fulcrum (residues 11–22 and 11'–22'), cantilever (residues 59–75 and 59'–75'), and the active ligand binding site organize different regions of the enzyme (**Fig. 3**). The active site of the protein is formed by dimerization of the two monomers and is crowned by two identical flexible glycine rich flaps. The volume of the active site and size is controlled by dynamics of the flaps (Piana et al., 2002a,b). As a member of the aspartic protease family, the protease contains a catalytic triad (Asp25-Thr26-Gly27) in both the chains keeping functional aspartate residues at the dimer interface. The Asp residues are essential both catalytically and structurally while the Thr and Gly residues functions are still unknown at this time and are buried in the active site (Mager, 2001).

Fig. 3 Schematic representation of the structure of HIV-1 protease (HIV-pr) bound to the ligand in the active site. Important regions of the protein are labeled. The homodimer protein is shown in violet and cyan ribbon structures.

Fig. 4 The structural distribution of the most common mutations associated with drug resistance in the HIV-1 protease. Mutations can occur anywhere in the protease structure. Mutations within the binding cavity are very conservative and operate by distorting the shape of the cavity. Conformationally constrained inhibitors have difficulties in adapting to the altered geometry and lose significant binding affinity. Adapted from Overcoming HIV-1 resistance to protease inhibitors. Drug Discovery Today. Disease Mechanisms | Infectious diseases, vol. 3, No. 2, 2006.

Mutations and Drug Resistance of HIV-Protease Inhibitors

Nevertheless, the HIV-pr-based therapeutic tactics have accomplished reasonable victory, but there are still some hurdles of serious side effects due to mutation-induced drug resistance. Currently, at least more than 50 mutations at near about 30 different codon positions of HIV-pr have been acknowledged. Lists of mutations that occur on the HIV-pr backbone are shown in [Fig. 4](#). A molecular level understanding of drug resistance requires the knowledge of both direct and indirect effects of mutation ([Johnson et al., 2010](#)). The mutant strains are increased in numbers by the drugs' abuse. Taking of numerous drugs has put selective pressure on the HIV leading to mutations and subsequent evolution of resistant variants ([Chen and Lee, 2006](#)). The mutations in HIV-pr are classified as those present near the active site (primary) and those appearing away from the active site (secondary). Both the

mutations affect the ligand/drug binding directly and indirectly by direct or indirect effects (Meher and Wang, 2012; Bandyopadhyay and Meher, 2006). There have been several studies (both experimental and computer simulation) indicating the importance of different mutations for the drug resistance in HIV-pr. Molecular dynamics (MD) simulation based approaches has been utilized by researchers worldwide to understand the HIV-pr 3D-structure dynamics and the drug resistance behavior (Piana *et al.*, 2002a, 2002b; Meher and Wang, 2012; Bandyopadhyay and Meher, 2006; Collins *et al.*, 1995; Hornak *et al.*, 2006; Meagher and Carlson, 2005; Ode *et al.*, 2006; Perryman *et al.*, 2004; Scott and Schiffer, 2000; Toth and Borics, 2006).

HIV-pr 3D-Structure and its Dynamics

HIV-pr 3D-structural dynamics is mainly from the contribution of its flap and flap elbow dynamics, which have the maximum movements for accession of ligands or substrates in its active site region. To date, researchers have analyzed the dynamics of both unliganded and liganded forms of the HIV-pr. In all of the liganded forms, the flaps are pulled in toward the bottom of the active site, leading to a flap curling-in event. In the unliganded enzyme, flaps are shifted away from the active site (Hornak *et al.*, 2006) making the flaps curl out. The contribution of residues in the active site region and flaps to the stability is more distinct in the liganded form than in the unliganded form (Kurt *et al.*, 2003). However, in HIV-pr the anticorrelation movements of the flap-active site distances and fulcrum-flap elbow distances is more notable (Perryman *et al.*, 2004).

Flap Movement and Dynamics

The flexibility of the flap tips (Gly48-Gly52 and Gly48'-Gly52') is known as flap dynamics. It opens and closes the flaps determining the cavity size. The conformational change in the flaps is correlated with structural reorganization of residues in the active site (Torbeev *et al.*, 2011). The mutations in flap region result in adjustment of the nonbonding interactions (van der Waals and electrostatic interactions) between the drugs and protein, subsequently helping drug resistance and rendering the drugs ineffective (Cai *et al.*, 2012). Thus numerous computational studies have made an effort to understand flap dynamics behavior. The effects of mutations on the 3D-conformational dynamics and reorganization of HIV-pr have been considered using MD simulations.

Mutation Effects on HIV-pr 3D-Conformation

JE-2147 (Yoshimura *et al.*, 1999) is an experimental peptidomimetic HIV-pr inhibitor developed by Pfizer (Fig. 5). It was measured to be more effective than other prevailing HIV-pr inhibitors, which is potent against a wide range of HIV-1, HIV-2 strains. JE-2147 retains exclusive resistance profile (Kar and Knecht, 2012a) with two major mutations I84V and I47V. Nevertheless, I84V is common for other related ligands, I47V appears to be very particular for JE-2147 (Bandyopadhyay and Meher, 2006). The influence of I47V mutation is explored with MD simulation. Simulation outcomes showed greater flexibility of the side-chain of mutant Val47 than that of WT Ile47 in chain B of HIV-pr (Bandyopadhyay and Meher, 2006). Structural investigation exposed that the existence of a flexible P2' moiety is significant for the effectiveness of JE-2147 concerning wild-type (WT) and mutant viruses. These data propose that the use of flexible mechanisms may open a new opportunity for designing protease inhibitors with greater efficacy.

Fig. 5 Molecular structure of the experimental inhibitor JE-2147. Four sites of interactions (P1, P2, P1', and P2') to the protein are labeled. Atoms are shown bonded to each other and are shown in solid lines. Atoms are shown in color as Carbon: Black, Oxygen: Red, Nitrogen: Blue and Sulfur: Gray.

Fig. 6 Configuration of the inhibitor TMC114, with the moiety bis-THF enclosed in square bracket. Atoms playing critical role in the interactions between the inhibitor and the enzyme HIV-pr have been denoted in bold letters. Reprinted from Meher, B.R., Wang, Y., 2012. Interaction of I50V mutant and I50L/A71V double mutant HIV-protease with inhibitor TMC114 (darunavir): Molecular dynamics simulation and binding free energy studies. *Journal of Physical Chemistry B* 116, 1884–1900. With permission from J. Phys. Chem. B and publisher American Chemical Society (ACS).

TMC114, a nonpeptidic compound ended by the bis-tetrahydrofuran (bis-THF) moiety shown in **Fig. 6**, is an enormously effective protease inhibitor (PI) to deal with the drug resistant HIV strains. With the presence of the terminal bis-THF moiety, it slightly differs from its chemical analog, amprenavir. Several studies have shed light on the drug resistance behavior of HIV-pr mutants towards TMC114 (Meher and Wang, 2012, 2015; Kar and Knecht, 2012a, 2012b; Kovalevsky *et al.*, 2006b; Tie *et al.*, 2007; Chen *et al.*, 2010; Vaishnavi *et al.*, 2017).

I47V mutation effect on JE-2147 and TMC114 binding

Vaishnavi *et al.* (2017) have investigated the binding of inhibitor TMC114 and JE-2147 to WT, and I47V mutant HIV-pr with all-atom MD simulations as well as MM-PBSA (molecular mechanics with Poisson–Boltzmann and surface area solvation) calculation. In I47V mutant apo HIV-pr, flap–flap distance was larger than WT or TMC114 and JE2 complexed mutant form (**Fig. 7**). The I47V-mutant complex HIV-pr has less curled flap tips and flexibility compared to WT and the apo mutant I47V. The mutant I47V decreases the binding affinity of I47V-HIV-pr to both the inhibitors (TMC114 and JE2), resulting in a drug resistance; due to an increased volume of the active site. (**Fig. 9**) However, the drug resistance of TMC114 to I47V mutant is heavier than JE-2147. The decrease of the binding affinity for the TMC114 complexed mutant I47V-HIV-pr is resultant of the the decreased electrostatic energy as well as van der Waals energy.

Comparing the apo form of protein WT vs. Mutant

The difference in RMSF (root mean square fluctuations) between the mutant and WT HIV-pr for each residue shows that the maximum changes in RMSF occurs between WT and mutant HIV-pr for the residues in the flap elbows of the two chains (35–42, 40'–42'), the dimerization region (Trp6), part of fulcrum (Gln18), and part of the cantilever region (67–69). MD simulation data from Vaishnavi *et al.* shows that the distance between the flap tip–active site and between flap tips has higher fluctuations for WT-APO and I47V-APO as expected. (**Fig. 8**).

Comparing the complexed form of protein WT vs. Mutant

In the complexed form HIV-pr, the difference in RMSF between WT and I47V-mutant is reduced for most of the residues. It was observed that regions around residues like Pro39-Trp42 (for TMC complex), and Trp6'–Arg8' (for JE2 complex) shows remarkable fluctuations compared to WT with more than 0.75 Å. The relatively larger RMSF of the mutant I47V-complex to its apo-form counterpart is likely to be arising due to larger conformational fluctuations and weaker binding. The distance between Ile50–Ile50' was determined to measure the relative motion of the flap tips. The distance variation between the complexed WT, I47V-TMC and I47V-JE2 HIV-pr was found to be fewer and tighter than apo HIV-pr (**Fig. 6**). Flap dynamics analysis also suggests larger active site volume in case of I47V-TMC and I47V-JE2. The results of these studies indicate that although the Ile50–Ile50' distance was similar in

Fig. 7 Time-series (above) and frequency distribution (below) plots for the flap tip-flap tip distances for the HIV-pr WT vs I47V mutant complexes and apo-type.

the complexed HIV-pr there still exist differences in the Asp25'-Ile50' distance, indicating the unique behavior of the two chains of a homodimeric enzyme like HIV-pr.

Molecular mechanism of drug resistance

In the I47V-mutant HIV-pr, the substitution of isoleucine with valine leads to the removal of a methyl group, which is likely to be decreasing the interaction with the central phenyl of TMC114 through C-H... π . Also, it is likely to be shortening the hydrophobic side chain and increasing the size of the active site, resulting in a reduced binding affinity to TMC114 and JE-2147. This change results in a decrease of van der Waals energy between Val47 and TMC114 comparative to the WT. However, for Val47 (47') the change shows a significant decrease in van der Waals energy, which could possibly be due to the lessening of C-H...O interactions between the Val47 side chains and the P2' position of JE-2147 and Val47 side chains and bis-THF (bis-tetrahydrofuran) moiety. The calculated binding free energies of complexes WT-JE2, I47V-JE2, WT-TMC, and I47V-TMC are -31.03 , -29.76 , -34.43 , and -30.73 kcal/mol, respectively, indicating that the binding free energy of WT is higher than the mutant I47V. The binding affinities (ΔG) of I47V-JE2 and I47V-TMC complexes decrease by 1.27 and 3.70 kcal/mol from their WT counterpart, suggesting drug resistance for both the mutant. Residues like Val47' in I47V-JE2 complex directly lowers the ΔG along with other residues like Gly49 and Val82' (Fig. 9).

Fig. 8 C α RMSF plot for the HIV-pr WT vs. I47V (above) and the difference is shown (below).

I50V and I50L/A71V mutations effect on TMC114 binding

The single mutation I50V and the double mutation (I50L/A71V) are recognized as two important residue point mutations in HIV-pr which affect protease inhibitors efficacy. Though both the mutations are located at critical region of HIV-pr structure, and their effect on other protease inhibitors have been studied previously, the effect of I50L/A71V mutation on TMC114 binding and the mechanism for drug resistance is still elusive. [Meher and Wang \(2012\)](#) explored the binding of TMC114 ([Fig. 6](#)) to WT, single (I50V) along with the double mutant HIV-pr with all-atom MD simulations and MM-PBSA calculation. The analysis of the apo and complexed HIV-pr indicates that the flap curling and opening events in double mutant I50L/A71V are more stable than WT or I50V. Further, the flap-flap and flap-active site distances also appears to be smaller in I50L/A71V when compared to that of WT or I50V ([Fig. 10](#)), resulting in a compact active site with smaller volume. I50V mutant reduces the binding affinity to inhibitor TMC114, causing drug resistance; while the I50L/A71V double mutant escalates the binding affinity ([Fig. 11](#)). It is remarkable to observe that the I50L/A71V escalates the binding affinity possibly by the stronger binding and better adaptability of the inhibitor TMC114 in its active site.

Comparing the apo form of protein WT vs. Mutant

Difference in B-factors or isotropic temperature factors could offer direct perceptions into the structural variations of HIV-pr in its WT and mutant forms. Each residue difference in B-factors amongst the mutant and WT HIV-pr is highest in the dimer interface region (6, 8 and 6', 8'), flap elbow-A (35, 37, 39–41), and flap-A (49–52). Analysis of the WT and mutant simulations

demonstrates that the flap–flap distance changes more in the WT and I50V than I50L/A71V (**Fig. 12(a)**), and flap–active site distance is measured to be smaller in I50L/A71V than in WT and I50V (**Fig. 10**). Therefore, both the flap–flap and flap–active site distance results recommend a neighboring movement of flaps in I50L/A71V comparing WT and I50V and possibly modifying the active site size reduced, which could help in improved binding of the TMC114 to the active site region. Improved binding of the TMC114 might be due to the increase in van der Waals (vdw) contacts between the TMC114 and the HIV-pr residues.

Comparing the complexed form of protein WT vs. Mutant

All the complexes (WT vs mutants) show similar fashion of dynamic features from the B-factor perspectives albeit a few exceptions. B-factor difference between the TMC114 complexed and apo HIV-pr for WT and mutant shows that the B-factor is reduced for most of the residues, specifically noticeable in the flap tip and flap elbow regions. It was observed that four regions around

Fig. 13 Graphical representation of H-bond propagation in the double mutant I50L/A71V and Asp25(25')-TMC114 flip-flop interaction. Red color arrow shows the path of propagation.

17 (17'), 41 (41'), 53 (53'), and 70 (70') exert the highest dynamic fluctuations. The slightly reduced B-factor of the I50L/A71V-complex may be described by the comparatively less conformational variations and stronger binding. The reduced flexibility in the inhibitor-binding site directs to the reduction in K_m , resulting in an increase in the affinity of the enzymes for the inhibitor and stronger binding (Zoldak *et al.*, 2004). In order to understand the flap dynamics behavior, the Ile50-Ile50' distance was studied. The difference among the complexed WT, I50V, and I50L/A71V HIV-pr was observed to be fewer and thinner than that of the apo HIV-pr (Fig. 12(b)). The utmost distinct motion for the HIV-pr complex was found to be the side-chain mobility of catalytic Asp25 about the inhibitor TMC114. It shows a flip-flop interaction of the Asp25 OD1/OD2 atoms with the O18 of TMC114 may be originated by the change in H-bonding pattern of the double mutant induced from A71V mutation (Fig. 13).

Molecular mechanism of drug resistance

In the I50L/A71V double mutant, the substitution of isoleucine to leucine, places the methyl group in an altered position, though structure of the side chain is not altered substantially. However, the replacement from alanine to valine adds two methyl groups to the backbone carbon in place of single methyl, which renders side chain bulkier. It is noted that, the change from Ala71 to Val71 in the cantilever region of the HIV-pr has not affected H-bond pattern; however, the H-bond between the residues Arg14' and Glu65' has been reduced (Meher and Wang, 2012). So, it is confirmed that the mutation A71V have no direct influence on the active site conformation and binding affinity. The mutation has allosteric effect on the binding affinity with change in the mobility of active site residues (Fig. 13). The resultant alteration in the conformation of the enzyme may affect its binding affinity to the inhibitor TMC114 to the protease.

In the I50V mutant HIV-pr, the replacement of isoleucine with valine leads to the loss of a methyl group. It lowers the contact with the central phenyl of TMC114, which leads to the decrement in the van der Waals energy between Val50 and TMC114. On the contrary, for Val50' the change displays a substantial decline in van der Waals energy (by 0.54 kcal/mol), which may be due to the falling of C-H...O interactions between the Val50' side chains and the O22 of TMC114. Fig. 14 confirms that the distance of C...O22 (3.4 Å) for I50V-HIV-pr is longer than that for WT and I50L/A71V-HIV-pr (4.1 and 3.6 Å, respectively), which is likely to be the reason for the less binding affinity and drug resistance.

V32I and M46L mutations effect on TMC114 binding

Meher and Wang (2015) investigated the binding of inhibitor TMC114 (Fig. 5) to WT, V32I mutant, and M46L mutant HIV-pr with all-atom MD simulations as well as MM-PBSA calculation. The analysis describes the resistance profile of both the mutants (V32I and M46L) with their 1T (single TMC114 bound alone to the active site region) and 2T (bound to the flap and active site region simultaneously) forms. The average flap-flap distance and flap tip-active site distances are longer for the M46L-2T HIV-pr complex as compare to the WT-1T and V32I-2T complexes suggesting an increased flexibility in M46L-2T, feasibly making the

Fig. 14 C-H...O interactions between the inhibitor TMC114 and the flap region amino acids (Gly49, Gly40', Ile/Val/Leu50, and Ile/Val/Leu50'). TMC114 in stick form is colored by the atom type, and residues are denoted as lines (green-WT; cyan-I50V; purple-I50L/A71V). Reprinted from Meher, B.R., Wang, Y., 2012. Interaction of I50V mutant and I50L/A71V double mutant HIV-protease with inhibitor TMC114 (darunavir): Molecular dynamics simulation and binding free energy studies. *Journal of Physical Chemistry B* 116, 1884–1900. With permission from J. Phys. Chem. B and publisher American Chemical Society (ACS).

Fig. 15 Energy components (kcal/mol) for the binding of TMC114 to the WT-1T, V32I-2T, and M46L-2T: Eele, electrostatic energy in the gas phase; Evdw, van der Waals energy; Gnp, nonpolar solvation energy; Gpb, polar solvation energy; Gpol = Gele + Gpb; TS, total entropy contribution; H = Eele + Evdw + Gnp + Gpb; $\Delta G = \Delta H - T\Delta S$. With permission from J. Mol. Graph. Mod. and publisher Elsevier.

active site capacity larger. From the binding free energies of all the complexes, it was gathered that both the 1T and 2T forms of the protease HIV-pr mutants show resistance to the inhibitor TMC114. Also, it came forth that the binding of the TMC114 on the flap region has inconspicuous impact on the binding affinity (Fig. 15).

Comparing the complexed form of protein WT vs. Mutant

The difference of RMSF (root mean square fluctuations) for the whole protein in its complexed form shows that the two mutations (V32I and M46L) cause more conformational changes of the HIV-pr near the flap elbows, fulcrum (Trp6, Ile15-Gly16 and Glu35-Lys41 & Trp6', Glu35' and Arg57'), and cantilever regions (Pro63-His69 and Ala67'), than the WT counterpart. To explore the relative motion of the flap tips, flap tip-flap tip distance was examined, where, the variation between the double bound and single bound V32I-2T and M46L-2T/HIV-pr was found to be different, the former being broader (Fig. 16). Further studies on flap dynamics studies revealed that there is a floppy flaps movement in M46L-2T in comparison to WT-1T and V32I-2T/HIV-pr structures. Flap RMSD analysis indicates that the binding of TMC114 on the flap -B of the mutant structures has only subtle effect on the flap dynamics.

Molecular mechanism of drug resistance

V32I mutation can lead to drug resistance by affecting the interactions between the amino acid side chains and the inhibitor. In the V32I-mutant HIV-pr, the substitution of valine with isoleucine leads to a gain of methyl group. It increases the interaction with the central phenyl of TMC114, and possibly increases the steric hindrance (unfavorable interactions), resulting in a reduced binding affinity to TMC114. This change results in an increase in total entropy contribution ($T\Delta S$) by about 3.42 kcal/mol for V32I-1T and 20.89 kcal/mol for V32I-1T as compared to the WT-1T/TMC114 HIV-pr complex (Meher and Wang, 2015). M46L mutation does not impact the inhibitor binding the active site region, but the atoms of Met46 residue may be forming H-bonds

Fig. 16 (a) Time-series plot and (b) frequency distribution plot for the distance between the flap tip (Ile50-Ile50') C atoms for the double bound TMC114 to HIV-1-pr mutants and single bound to WT. Exploring the drug resistance of V32I and M46L mutant HIV-1 protease to inhibitor TMC114: Flap dynamics and binding mechanism. *Journal of Molecular Graphics and Modelling* 56, 60–73. With permission from J. Mol. Graph. Mod. and publisher Elsevier.

Fig. 17 Comparative schematic view showing the binding of TMC114 in the allosteric site (flap region) for mutants (V32I-2T and M46L-2T) does not influence the binding affinity of the system, which can be compared with the mutants (V32I-1T and M46L-1T). Reprinted from Meher, B.R., Wang, Y., 2015. Exploring the drug resistance of V32I and M46L mutant HIV-1 protease to inhibitor TMC114: Flap dynamics and binding mechanism. *Journal of Molecular Graphics and Modelling* 56, 60–73. With permission from J. Mol. Graph. Mod. and publisher Elsevier.

with substrate analogs (Tie *et al.*, 2005). Hence, M46L mutation can have effect on binding affinity indirectly via the weakened hydrophobic interactions (Kovalevsky *et al.*, 2006a). This alteration results in an increase in total entropy contribution (TAS) by about 2.64 kcal/mol for M46L-1T and 16.83 kcal/mol for V32I-1T as compared to the WT-1T/TMC114 HIV-pr complex (Meher and Wang, 2015). Therefore, the entropy penalty ultimately compresses the binding affinities and elicit the drug resistance for the V32I and M46L mutations. However, binding of TMC114 in the allosteric site (flap region) does not contribute much in the total gain in binding affinity of the system, due to significant entropy loss leading to the lower binding free energies (Fig. 17).

Future Directions

The synergy between mutation and conformational dynamics has exposed the mechanisms of drug resistance. There are potential directions that can be discovered on the basis of the current work.

- 1) Information regarding the placing of a larger group at the P2' position of JE-2147 and also replacement of a group at the position of O18 in the TMC114 structure will be helpful in drug designing. One can proceed for the structural improvement of TMC114 and JE-2147 in vitro and in silico as well based on the combinatorial chemistry.
- 2) Binding of the inhibitor (TMC114) in the flap region does not improve the binding affinity of the system. This understanding will promote the development of drugs/inhibitors targeting mostly to the active site region and not to the flap region. However, targeting to other important regions like flap elbow and fulcrum may help in development of allosteric site inhibitors, which may promote the total gain in binding free energies of the system.

Concluding Remarks

MD simulation has been a tool of tremendous importance and offers generous understandings into the mechanistic features of macromolecular 3D-conformation and dynamics at atomic level. It illuminates the mechanisms of drug binding and resistance profile towards HIV-pr. The study steered to the outcome that 3D-conformational dynamics of HIV-pr is affected by the change in 3D-data coordinates in the protein crystal structure due to mutations that have an important role on HIV-pr conformation and dynamics. Conclusively, the understanding of the molecular basis of drug resistance is a difficult job. However, the result of this study as well as other prior revisions on HIV-pr may offer insightful knowledge with which to design favorable and potent drugs/inhibitors.

Biographical Sketch

Dr. Biswa Ranjan Meher is an Assistant Professor at the Computational Biology and Bioinformatics Laboratory, Department of Botany, Berhampur University, Berhampur, Odisha, India. He received his PhD in Biotechnology from Indian Institute of Technology, Guwahati, India. He worked as a Post-Doctoral Researcher at different US universities like the University of Kansas (KU), Kansas; Albany State University (ASU), Georgia; and University of Richmond (UR), Virginia. He also worked as a DS Kothari Post-Doctoral Fellow (DSKPDF) in the Department of Biochemistry at the Indian Institute of Science, Bangalore, India from 2014 to 2016. Before joining his current position, he also served as an Assistant Professor in the DBT-BUILDER Programme at the Centre for Life Sciences, Central University of Jharkhand, Ranchi, India from 2016 to 2017. He has published his research work in reputed international journals like *Journal of Physical Chemistry B*, *Journal of Biomolecular Structure and Dynamics*, *PLoS One*, *Chemical Biology and Drug Design*, *Journal of Molecular Graphics and Modeling*, and others. His current research interests include nanomedicine development and applications, molecular modeling and simulations of biomolecules, understanding the protein conformations through structure network analysis, and application of computational tools to solve biological problems.

Dr. Venkata Satish Kumar Mattaparthi received his PhD in Biotechnology from Indian Institute of Technology Guwahati, Assam, India in 2010. From 2010 to 2012, he was with the Centre for Condensed Matter Theory (CCMT), Department of Physics, Indian Institute of Science Bangalore, India. He is currently working as Assistant Professor in the Department of Molecular Biology and Biotechnology, School of Sciences, Tezpur University, Assam, India. His research interests include understanding the functioning of intrinsically disordered proteins (IDPs), pathways of protein aggregation mechanism in neurodegenerative diseases like Alzheimer, Parkinson, etc., and also the features of protein–RNA interactions using computational techniques. He has published his research in reputed international journals like *Journal of Biomolecular Structure and Dynamics*, *PLoS One*, *Journal of Physical Chemistry B*, *Biophysical Journal*, *Journal of Bioinformatics and Computational Biology*, and others.

Dr. Seema Patel, MSc, MS, PhD, is a graduate of Indian Institute of Technology Guwahati, India and San Diego State University, USA. She has worked in industrial microbiology and then on in silico clinical microbiology. She has served as Assistant Professor in Lovely Professional University, India and as Research Assistant in San Diego State University. She has been in the biomedical research field since 2007, and has written or edited eight books, and published more than 100 papers on microbiology, food science, bioinformatics, enzymology, immunology, endocrine disruption, and correlated topics.

Megha Vaishnavi, has worked as a Junior Research Fellow at the Computational Biology and Bioinformatics Laboratory at the Centre for Life Sciences, Central University of Jharkhand with the DBT-BUILDER Programme under the guidance of Dr. Biswa Ranjan Meher. She is a Post-Graduate in Microbiology from Central University of Rajasthan and graduate in Biotechnology from IPS Academy Indore, Devi Ahilya Vishva Vidyalaya (DAVV). Her research interest includes molecular modelling and simulations of therapeutically significant biomolecules and structure-based drug design.

Dr. Sandeep Kaushik is a passionate computational biologist with a wide exposure of computational approaches. Presently, he is carrying out his research as an Assistant Researcher (equivalent to Assistant Professor) at 3B's Research Group, University of Minho, Portugal. He has a PhD in Bioinformatics from National Institute of Immunology, New Delhi, India. He has a wide exposure on analysis of scientific data ranging from transcriptomic data on mycobacterial and human samples to genomic data from wheat. His research experience and expertise entails molecular dynamics simulations, RNA-sequencing data analysis using Bioconductor (R language based package), de novo genome assembly using various software like AbySS, automated protein prediction and annotation, database mining, agent-based modeling, and simulations. He has a cumulative experience of more than 10 years of programming using PERL, R language, and NetLogo. He has published his research in reputed international journals like *Molecular Cell*, *Biomaterials*, *Biophysical Journal*, and others. Currently, his research interest involves in silico modeling of disease conditions like breast cancer, using an agent-based modeling and simulations approach.

Structural Genomics

Introduction

Computational means of assigning function have been crucial for the annotation of the numerous genomes that are being sequenced. Without a computational function annotation system, much of the genome sequences generated would remain isolated voluminous non-sensical digital outputs. The primary means of assigning a function to a new open reading frame (ORF) or coding sequence (CDS) has been sequence alignment.

The function of a known protein sequence can be transferred to its homolog once the sequence similarity is considered adequate to infer shared function. The basis of such a function inference is the fact that the function of proteins are dependent on their three-dimensional (3D) structures. The work of Anfinsen (1972) has demonstrated that the information needed for a protein to fold into its functional 3D structure is contained within the sequence of amino acids that make up the polypeptide. The entropic (disordered) state of the different amino acids in a newly synthesized polypeptide chain drives it to fold into the 3D structure. Chothia and Lesk (1986) had determined that sequence similarity at 30% is enough for a protein to share similar folding and retain a similar function. This has thus been used as a cutoff point for many sequence alignments when assigning function from similarity.

Nevertheless, there remain vast numbers of sequences that have uncharacterized function. For many genome annotations, predicted ORFs with no characterized homologs have been assigned the label 'hypothetical protein'. Solving the structure of a hypothetical protein can be enough to identify any folding similarities to structures already available in the Protein Data Bank (PDB) (Dey *et al.*, 2018; Laskowski *et al.*, 2018) and thus point to potentially similar functions. The PDB is the central repository for structural coordinates of biological macromolecules that have been made publicly accessible. Visual examination and computational analysis of a protein's structure may yield clues regarding its function. If function characterization could be potentially achieved by acquiring the structures of the many proteins with yet to be determined functions, then a systematic high throughput means of acquiring such structures would ultimately accelerate such efforts.

Developments and progress in macromolecular structure determination methods, especially in X-ray crystallography, and lately in cryo-electron microscopy, have resulted in more than 130,000 structures being deposited in the PDB. The bulk of this number (approximately 90% in November 2017) were determined using X-ray crystallography. The availability of numerous genome sequences and the progress made in structural biology have therefore led to large scale projects with the specific objectives of determining the 3D structures for proteins encoded in these genomes, such an approach has been termed as structural genomics. For many of these projects, emphasis was placed on the hypothetical proteins that had no known sequence homologs with characterized functions. One of the earliest test case for structural genomics was the MJ0577 hypothetical protein structure of the hyperthermophile *Methanococcus jannaschii* that was solved to a high resolution (Zarembinski *et al.*, 1998). The structure of MJ0577 was found to contain an ATP molecule, which directed the function search of the protein that was later confirmed as an ATPase (Zarembinski *et al.*, 1998).

In this article, we review and discuss computational strategies currently in use for structural genomics, specifically for structures solved by X-ray diffraction of protein crystals. While the protein production and crystallography remain as molecular biology and chemistry problems, the selection of targets to be fed into a structural genomics pipeline and the analyses of the resulting structures are computational biology problems.

Background

Defining Structural Genomics

There are currently different definitions available for the term structural genomics. Several often used definitions are: (i) an effort to describe 3D structure of every protein encoded in a genome via experimental approaches or computational modelling or a combination of both; and (ii) knowledge on the structural organization of the genome thus allowing for all the genes in a genome to be located and characterized. This article will touch on the former, but will only proceed in depth for a subset, which is the solution of structures via experimental means. The second will not be discussed under this topic. In a way, the definitions have overlaps and all are arguably correct; however, these differences and similarities will not be discussed in depth here.

The Extent and Realities of Structural Genomics in Practice

Methods used for determining the 3D structures of proteins have improved tremendously over the past decade. The bulk of the PDB is composed of structures solved through X-ray crystallography with the remainder consisting of coordinates acquired through nuclear magnetic resonance (NMR) spectroscopy and cryo-electron microscopy (Cryo-EM). The X-ray crystallography technique is the most common method used in structural genomics because it can be applied to a wide range of protein sizes and types, including membrane proteins.

An increase in the computational capacity to process the theoretical folding of protein sequences into their 3D structures means that the generation of 3D structures for every protein in a genome is moving closer towards reality. Nevertheless, such capability is not expected in the foreseeable future. However, even for a wholly computational structural genomics approach, it may not be necessary to compute all the CDS in a target genome because for some proteins, an experimentally solved structure may already exist (Baugh *et al.*, 2013).

Similarly, it may not be necessary to experimentally determine the structure for every CDS in a genome because they are already available in the PDB, either for the same organism from another work, or as a homolog from another source. The constraints for an experimental structural genomics approach is grounded in the reality of costs and other limitations that include but are not limited to: the ability to clone, express, purify and crystallize the protein; followed by a requirement for the crystal to diffract and the data to be processable. This process of molecular biology by attrition can result from an initial starting point being thousands of CDS ending with perhaps solved structures that number in the hundreds or even less (Franklin *et al.*, 2015).

The structural genomics process gradually reduces the initial number of target genes acquired from the genome sequence via a systematic process up to the point of coordinate data acquisition for the encoded proteins. As such, this process can be made into a pipeline (Fig. 1) that begins by taking in all the predicted CDS from the genome sequence and proceeding with steps that can then be defined specifically to fit a project's requirements and objectives. For example, for many groups, a logical first step is to identify CDS that code for possibly insoluble proteins; in practice, this is done by identifying membrane proteins (Fig. 1). The next step may be to filter the CDS for those that have very similar examples already available in the PDB. The cut-off for similarity can vary depending on the interests and requirements of the project.

The filtering process can also be intervened from the start to begin with a smaller subset; for example, only CDS that have been annotated as hypothetical proteins can be selected for input into the structural genomics pipeline. Other examples would be to target for a selection that may be of existing focus in a research group – for example, potential drug targets (Franklin *et al.*, 2015; Fedorov *et al.*, 2007). Nevertheless, it must be noted that even for sequences that were initially targets in a structural genomics pipeline, but do not end up as crystallographic structures, may actually have varying degrees of useful functional characterization as a result of having passed through the pipeline (Ahmad *et al.*, 2015; Yusof *et al.*, 2016; Hashim *et al.*, 2013; Ramli *et al.*, 2013).

Although we do not discuss structures solved by NMR and cryo-EM, switching the experimental method that the pipeline feeds from protein crystallography to either NMR, cryo-EM or a combination of all three methods can also be carried out. Thus structural genomics in the present context can be an integration of all available methods to acquire 3D structure data. Similar to the case of filtering the ORFs for the purpose of crystallography, the pipeline can be redirected to identify targets for these other methods – such as identification of smaller molecular weight proteins that would be amenable to structure solution by NMR.

Fig. 1 The overall structural genomics process begins with computational filtration to get target genes and proceeds to solved structures via experimental means. The general filtration begins by removing genes that have transmembrane regions, are insoluble, have more than 20% of low complexity regions and coils. This is followed by removing predicted CDS with lengths less than 50 or more than 700 amino acids and have more than 30% sequence identity with entries in the PDB database.

Systems and/or Applications

A pipeline to process a genome sequence for the purpose of structural genomics can be assembled using proven tools (Table 1). Due to the potential volume of sequences that will be analysed, a local or fit for purpose installation of the programs required would be ideal. This would thus prevent the pipelines engineered for such projects from overloading publicly available servers at the expense of other users. Nevertheless, when such a practice is not possible, care and due consideration of other users of the service should be exercised when scheduling input submissions. As discussed previously (Section “The Extent and Realities of Structural Genomics in Practice”), the starting point of the pipeline would vary depending on the requirements and capacity of the project.

A filter for insoluble proteins, which would be a logical feature and starting point for many projects, would obviously be unsuitable if the project were to actually include the solution of membrane proteins among its objectives. In order to perhaps maximize the return of the project in terms of finding novel folds or characterizing undescribed functions for hypothetical proteins, some projects would opt to further restrict the targets to sequences that are unrepresented in the PDB. This is usually done by employing a 30% sequence identity cutoff or dipping as low as 25% identity (Nair *et al.*, 2009).

For perhaps many projects, these two initial steps of screening for membrane and membrane associated proteins would be adequate to proceed on to the process of elimination from the pipeline by experimental attrition. However, it is also possible to specifically filter for a subset of sequences that contain either N-terminal or C-terminal associated membrane insertions. This is done by identifying whether the first and last thirty residues could potentially be membrane embedded by plotting hydrophobicity plots or predicting transmembrane helices for these sections of the sequence for every CDS in the genome (Marsden *et al.*, 2007). Once identified, these sequences are then cloned and expressed without the predicted transmembrane anchor. Although this does not guarantee solubility, this does increase the initial set of targets while at the same time allowing for the structures of membrane anchored proteins to be solved.

At this stage, the project can then proceed to the non-computational steps highlighted as in Fig. 1. A computational component can then be integrated again at the point where the structure data is available in PDB format. This second phase of the computational analysis will include structural similarity comparisons and in depth structural analysis. It is common practice to identify fold similarities for a solved structure once the final structure file has been acquired. Here we will discuss aspects of computational analysis on the structure but will exclude discussion of in depth visual scrutiny of the structure using molecular graphics.

In most cases, a fold similarity search, such as by the DALI program (Holm and Laakso, 2016) is sufficient to identify other structural homologs. There are however hypothetical proteins that have no similarity to known folds or are matched to structures of proteins with uncharacterized functions (Nadzirin and Firdaus-Raih, 2012). In such cases, the lack of fold similarity will not allow for association with any known structural features than can in turn provide clues as to possible function to be made. In such a situation, computer programs that can carry out structural analysis independent of any homology requirements can be used.

There are several computer programs that work by identifying similarities of 3D substructures or motifs that can bypass the necessity to have fold similarity in order to make a functional association. Many of these methods are able to search and/or

Table 1 Selected programs and their applications that can be integrated into a structural genomics pipeline. A listing of the seven programs or web servers for sequence alignment, transmembrane prediction, protein solubility prediction, coils region prediction, low complexity region prediction and a protein structure database

Function	Program/server	Method/content	URL
Sequence alignment	BLAST	Protein sequence alignment to protein sequence in PDB database.	https://blast.ncbi.nlm.nih.gov/Blast.cgi
	MUSCLE	Iterative alignment of protein sequences to get conserved residue/motif.	https://www.ebi.ac.uk/Tools/msa/muscle/
Transmembrane prediction	TMHMM	Predicts TMs using HMMs (edit this) – just providing an example.	http://www.cbs.dtu.dk/services/TMHMM/
Protein solubility prediction	PROSOII	Predict solubility based on a classifier by two-layered structure in which the output of a primary Parzen window model for sequence similarity and a logistic regression classifier of amino acid k-mer composition serve as input for a second level logistic regression classifier to exploiting subtle differences between soluble proteins from TargetDB and the PDB and notoriously insoluble proteins from TargetDB.	http://mbilij45.bio.med.uni-muenchen.de:8888/prosolII/prosolII.seam
Coils regions prediction	COILS/Coiled-coil prediction	Predict coils regions using MTK and MTIDK matrices both assign high probabilities to known coiled coils segment.	https://embnet.vital-it.ch/software/COILS_form.html https://npsa-prabi.ibcp.fr/cgi-bin/primaln_lupas.pl
Low complexity region prediction	SEG	Predict low complexity region by the SEG algorithm represent compositionally biased regions based only on residue composition and taking into account the improbability of appearance of such sequences.	http://mendel.imp.ac.at/METHODS/seg.server.html
Protein structure database	Protein Data Bank (PDB)	A crystallographic database for the three-dimensional structural data of large biological molecules, such as proteins and nucleic acids.	https://www.rcsb.org/pdb/

compare directly a query arrangement (Debret *et al.*, 2009; Nadzirin *et al.*, 2012, 2013) against a database or take a query structure and compare it against a database of motifs (Nadzirin *et al.*, 2012). There are also services that allow for annotation of specific sites such as binding sites (Konc and Janezic, 2017).

Analysis and Assessment

The need to experimentally determine a structure can be made based on several factors. In situations where detailed information of the differences for atomic level interactions are required, such as for drug development applications, an experimentally solved structure is necessary. It is therefore not uncommon for structural genomics projects to target not only CDS that have less than 30% sequence identity to examples in the PDB but also proteins that are deemed as important where mechanistic details at the atomic level can still be different even though the proteins are homologous. However, for applications where the investigator would like to select residues for site directed mutagenesis as part of a larger characterization effort, then high quality predicted models may suffice (Bhattacharya *et al.*, 2007).

We provide an example where the sequence for an arginase acquired from the genome of *G. antarctica* (Firdaus-Raih *et al.*, 2018), a psychrophilic yeast, was predicted and compared to the structure that was solved by molecular replacement of the X-ray diffraction data (PDBID: 5ynl). The sequence identity between the *G. antarctica* arginase and the reference used for molecular replacement, a human arginase (PDBID: 4hze), is 45%. In this particular case, the decision was made to solve the structure of the arginase despite the sequence identity being higher than the 30% cutoff point used for most of the other targets in the project. It was deemed necessary to acquire a structure that could provide atomic level details of the function as they may be specific to yeasts, psychrophiles or simply unique to *G. antarctica*.

To make a comparison of the differences that could arise from a computationally predicted model, we compared the solved structure to one that was predicted using SWISS-MODEL (Biasini *et al.*, 2014). As expected, the prediction was able to generate the correct fold with discernible disagreements between the two structures only in the loop regions with the compared structures having an RMSD value of 1.06 Å. When the computed model was compared to the template, the differences were much lower at an RMSD of 0.31 Å. It is clear that the model is biased towards the template than the experimentally determined structure (Fig. 2).

We then examined how much an effect the modelling had on the side chain arrangements when the model was compared to the template and the experimental structure. For this comparison, eleven residues that have been reported to be involved in metal coordination and arginine binding were selected. As observed for the folding, it is clear that the predicted model is more biased to the reference used (Fig. 3). Nevertheless, with the exception of D194 and E288 – two of the putative arginine binding residues – the arrangement of side chains for the other nine residues were generally similar and could be seen as having acceptable overlaps. In E288, the side chains ended up in opposite directions despite the C-alpha position generally overlapping. For D194, the general position of the residues in the experimental structure and model were the same, but neither the side chain or the C-alpha position overlapped.

These limitations of protein structure prediction are well understood. Here, we demonstrate the fact that even when a homologous PDB structure is available at 45% sequence identity, an experimentally determined structure will still have valuable atomic level details that cannot be adequately transferred via comparative modelling. It is clear that despite the fold conservation, it is the intricate details that could be the factor in understanding mechanistic differences between homologous proteins. This in a way affects the target selection criteria for the structural genomics pipeline. As a result, manual intervention of the pipeline may allow for a more refined target list as opposed to a target list generated wholly based on pre-determined values and computed without expert curation.

Fig. 2 Comparison of *G. antarctica* arginase structure generated from protein crystallography against a predicted model generated by SWISS-MODEL. The superposition of *G. antarctica* arginase structures between (A) predicted 3D model (dark blue) with X-ray crystal structure (gold) (RMSD: 1.06 Å/243 C α) and (B) predicted 3D model (dark blue) with the template used for prediction (PDBID:4ity) (cyan) (RMSD: 0.31 Å/300 C α). Superposition was done using CCP4MG.

Fig. 3 Superposition of active site residues between (a) *G. antarctica* arginase structure solved by X-ray crystallography (gold) (PDB template used: 4hze) against the SWISS-MODEL predicted arginase (light blue) and (b) The SWISS-MODEL predicted arginase (light blue) against the template used for prediction (PDBID: 4ity). Active site residues are labeled based on the numbering of *G. antarctica* arginase crystal structure. The strictly conserved putative metal coordinating residues in *G. antarctica* arginase are H112, H137, D135, D139, D243 and D245 and several conserved putative arginine binding residues are D139, N141, S148, H152, D194 and E288.

Illustrative Examples and Case Studies

Burkholderia pseudomallei

Burkholderia pseudomallei is a pathogenic soil bacteria that causes the disease melioidosis. At the initial time of writing (circa November 2017), there were 237 PDB entries for *B. pseudomallei* in the PDB. Filtering those for structures that have less than 95% sequence identity retrieved 99 PDB entries. Due to the use of mutant structures as a means to characterize functional mechanisms, this reduced number is most likely the actual count for unique *B. pseudomallei* structures in the PDB. Of the 237 structures, 51% (121 entries) were deposited by the Seattle Structural Genomics Center for Infectious Disease (SSGCID) (Myler *et al.*, 2009). The number submitted by the SSGCID could be reduced to 63 entries when a sequence identity filter of 95% was used.

The SSGCID is a National Institute of Allergy and Infectious Diseases (NIAID) consortium applying structural genomics approaches for identifying potential drug targets (Stacy *et al.*, 2011). In the search for drugs against *B. pseudomallei*, the SSGCID embarked on a combined functional and structural genomics approach to identify essential proteins and solve their structures (Baugh *et al.*, 2013). This effort involved experimental identification of essential genes using transposon mutagenesis in *Burkholderia thailandensis*, a phylogenetically similar member of the *Burkholderia* genus. With 406 putative essential genes identified, an ‘ortholog rescue’ strategy was employed for difficult targets by integrating seven other *Burkholderia* species into the pipeline as sources for orthologous proteins.

These efforts resulted in 31 structures of which 25 proteins have properties of a potential antimicrobial drug target. Although the identification of essential genes was experimentally carried out using transposon mutagenesis, the genomes of the *Burkholderia* species were compared to examples of known essential genes from UniProtKB (see “Relevant Websites section”) and the Database of Essential Genes – DEG (see “Relevant Websites section”) (Zhang *et al.*, 2009). The identified targets were also used to identify the existence of human homologs using BLASTP – the results of this was used to further filter the target list to only proteins that did not have any human homologs.

The work that reported the discovery of *Burkholderia* lethal factor 1 (BLF-1) (Cruz-Migoni *et al.*, 2011) started on a similar footing. The project was aimed at identifying *B. pseudomallei* essential genes, as well as novel pathogenicity factors. Despite some similarities to the SSGCID initiative, the drafting of the target list was carried out differently. Instead of using transposon mutagenesis, potential essential genes were computationally identified based on their homologs in the DEG resource. An additional dataset of genes that were annotated to encode hypothetical proteins was also generated. The essential genes homologs and the hypothetical proteins were then cross-referenced against the proteomic profiles of *B. pseudomallei* and *B. thailandensis* reported by Wongtrakongate *et al.* (2007). *B. thailandensis* is non-pathogenic, therefore proteins present in the *B. pseudomallei* proteome but absent in the *B. thailandensis* proteome were assumed to have potential roles in pathogenesis – these were then selected as targets for the pipeline. The BPSL1549 protein was found to be present in the 2D gel electrophoresis data of *B. pseudomallei* but absent in that of *B. thailandensis* thus leading to its selection for structure determination.

For decades, conclusive evidence for the pathogenicity and virulence factors of *B. pseudomallei* had eluded investigators (Stone, 2007). The BPSL1549 structure, which was renamed to BLF-1, had fold similarities to the catalytic domain of *Escherichia coli*

cytotoxic necrotizing factor 1 (CNF-1) (Cruz-Migoni *et al.*, 2011). The solution of the BLF-1 structure led to the identification of its substrate, the eukaryotic translation eIF4A, hence characterizing the role of BLF-1 in the disruption of protein synthesis in its host.

Glaciozyma antarctica

Glaciozyma antarctica is an obligate psychrophilic yeast that is able to survive at temperatures below 20°C. From its genome annotation, a total of 7857 genes were predicted (Firdaus-Raih *et al.*, 2018). Target genes for structural genomics were then chosen by filtering out 1610 genes encoding transmembrane regions, 4874 proteins predicted to be insoluble, 198 proteins computed to have low complexity regions and 23 proteins where coils make up more than 20% of the total sequence. These filtering steps also selected genes that have lengths of between 50 and 700 amino acids and no similar examples in the PDB at a sequence identity of 30% or lower which produced 453 target genes with 53% of this number having been annotated as hypothetical proteins.

Several target genes from *G. antarctica* were further crystallized and six of the structures had been successfully solved at the time of writing with three having been deposited in the PDB (PDBIDs: 4xxf, 5yhp, 5ynl). A resource that tracks the progress of target CDS for structure solution is available as part of the GlacIER (*Glaciozyma antarctica* Integrated Exploration Resource) database (see “Relevant Websites section”). This is perhaps another aspect that a computational and informatics based approach can be integrated into structural genomics. In this case, a simple MySQL database was made accessible via a web interface that allowed members of the project as well as the public varying levels of access to the data. Users of the database can thus track the progress of the targets as they proceed through the pipeline. Undoubtedly, more complex enterprise level management of such pipelines are in use by larger structural genomics consortia that work on multiple target organisms, however, the GlacIER database demonstrates that a small group in extended collaboration with several other labs can also execute a structural genomics project.

Discussion and Future Directions

Although the bulk of the work done in structural genomics consists of experimental work to produce proteins and generate 3D structure coordinate data, it is clear that extensive sequence database searching needs to be carried out during the identification of targets for the pipeline. Computational approaches are once again called upon for analysis of the 3D structures once they become available. While most structural genomics pipelines that can be found in the literature adopt a similar structure to that presented in Figs. 1 and 3, this is expected to evolve as the resolutions of structures acquired using cryo-EM get higher.

It is not expected for cryo-EM to supplant protein crystallography in providing the bulk of the 3D structures in the PDB; however, future structural genomics projects may employ all three approaches in order to provide a wider coverage of the structures that can be acquired from an available genome sequence. These would thus require the target selection process to take into account the specific requirement for each method and no longer be highly dependent solely on protein solubility. Informatic approaches would be required to provide decision making tools to identify targets and estimate the requirement and/or necessity of solving specific homologous structures. The pipeline may also evolve further to include computational methods of structure determination.

Closing Remarks

The structural genomics pipeline and specific filters enable what can be an expensive endeavour to have a reduced workload and cost. This allows for smaller and less well funded groups outside of large structural genomics consortia to also practice structural genomics as discussed in the case studies examples.

Introduction

Rheumatoid arthritis (RA) is a chronic inflammatory disease that is characterized by symmetrical pain in one or more joints (Landre-Beauvais, 2001). The symptoms usually start with stiffness in the morning, followed by joint tenderness and swelling. The number of affected joints varies, but most of the disease development involves five or more joints, including both small and big joints. Since its identification, RA has been the cause of joint inflammations in 0.5%–1% of the world's population (Gabriel, 2001).

The number of people diagnosed with RA in year 2008 has been estimated to be nearly 1.3 million in the United States (Helmick *et al.*, 2008). The affected patients have a low health-related quality of life due to physical damages induced by the disease (Salaffi *et al.*, 2009). This caused difficulties for the patients to perform their routine activities, and for some, it resulted in losing their jobs. With the assumption that human life span increases every year, it is expected that the frequency of correctly diagnosed patients with RA will increase in the future.

RA is regarded as an autoimmune disease (Davidson and Diamond, 2001). The word 'autoimmune' is a combination of two separate words that is auto and immune. Auto refers to self, while immune means the immune system. Therefore, autoimmune disease can be easily understood as a disease that is triggered by the abnormal response of the immune system against one's substance or tissue that is naturally presented in the body. In the case of RA, the target is the joint and the tissues that surround it. The onset of RA is caused by the stimulation of the immune system that is triggered by foreign substrates that mimic the joint cells (Davidson and Diamond, 2001). As a defensive mechanism, the immune components start to attack the invaders and coincidentally, the joint cells too. This in turn, causes the swelling of the synovial membrane, leading to joint inflammation.

Over the past 30 years, several classes of drugs have been introduced to treat RA. Routinely, these drugs are prescribed after the first tissue is damaged. The main aim is to minimize RA joint inflammations, but the drugs do not treating the underlying causes. At present, three classes of drugs are commercially available, namely corticosteroids, non-steroidal anti-inflammatory drugs (NSAID) and disease-modifying anti-rheumatic drugs (DMARD). Depending on the disease severity, an appropriate drug is prescribed and the patient status is reviewed from time to time. Among all three drugs classes, DMARD is the most commonly prescribed medication for RA patients. An example of a drug from this class is methotrexate (MTX) (Aletaha *et al.*, 2010). Although it is effective in relieving RA symptoms, the mechanism of action of MTX in treating RA remains unclear. A major drawback of MTX is that it can cause the development of multiple side effects on the central nervous, hepatic, pulmonary, hematologic and gastrointestinal systems especially in long-term usage (Smolen *et al.*, 2005). This drug also has a toxicity issue, which is why MTX was discontinued in certain, more susceptible RA patients (Smolen *et al.*, 2010).

RA is not be a fatal disease, however, severe and unmanageable conditions may arise that gradually disrupts overall human function, and thus, the quality of life (Salaffi *et al.*, 2009). Long-standing RA patients have an increased risk of suffering multiple health problems. Therefore, it is crucial to diagnose RA at an earlier stage of the disease; so that treatment can be administered sooner and the major damage of joint tissues can be prevented. Recent interest has been focused on citrullinated peptides, which is a true RA antigen (Schellekens *et al.*, 1998, 2000). Detection of autoantibodies against this type of antigen is more specific and sensitive than the current RA serological marker, Rheumatoid Factor (RF). This makes the antibodies correspond to the citrullinated peptides, name Anti-Citrullinated Peptide Antibody (ACPA) a suitable clinical marker to be developed (Wegner *et al.*, 2009).

Citrulline can be produced from an arginine residue in a peptide/protein (van Venrooij and Pruijn, 2000). Since the overall conversion involves the replacement of an imine group to a carbonyl group, the chemical reaction is often referred to as deimination (Fig. 1). The reaction is catalyzed by an enzyme called Protein Arginine Deiminase (PAD). In normal physiology, citrullinated peptides are present in proteins such as myelin sheath and histone (Jones *et al.*, 2009). In the case of RA, irregular expressions of citrullinated peptides (and hence, ACPA) have been reported (Hoet and van Venrooij, 1992; Hoet *et al.*, 1991; Vincent *et al.*, 1999). Traces of the peptides and the enzyme catalyzing the reaction, PAD type 4 (PAD4) are found in the sera and joints of the patients (Kinloch *et al.*, 2008). This triggers the autoimmune response, resulting in joint inflammation. Therefore, suppression of the citrullination pathway has been hypothesized to be a strategic yet specific way to slow down the disease. An ideal approach is to modulate the protein that catalyzes the reaction, namely PAD4.

Fig. 1 Enzymatic conversion of peptidylarginine into peptidyl citrulline.

Related Autoantibodies in RA Diagnosis

RA is indeed a tricky disease to diagnose. This is because the clinical symptoms are visible only after the first tissue damage. Luckily, during the disease development, the immune cells of the RA patient excrete various types of autoantibodies that can be used as indicators. There are a numbers of excellent reviews regarding RA-related autoantibodies and their biochemistry (Boekel *et al.*, 2002; Vossenaar, 2004).

Rheumatoid Factor (RF) is the first autoantibody found in RA patients. It was described in the late 1930s and is still used as one of the criteria for diagnosing RA (Aletaha *et al.*, 2010; Arnett *et al.*, 1988). It is reactive towards the tail (or known as Fc portion) of immunoglobulin G (IgG), which is an antibody that protects the human body from infections. This factor however, has also been found in many other diseases involving immune reactions and infections (Boekel *et al.*, 2002). To a certain extent, this antibody has been found in 5% of healthy population, in which the percentage increases up to 30% in healthy elderly. It is interesting to note that not all RA patients would exhibit this formula. This results in the classification of 'seropositive' or 'seronegative' RA groups. The former are the ones who demonstrated physical symptoms with RF antibodies, the latter are those who manifested the symptoms with no evidence of elevated RF values (Arnett *et al.*, 1988). Altogether, this indicates that the RF had low specificity and sensitivity; hence it can not be used as a single indicator in RA diagnosis.

In recent years, the emergence of autoantibodies towards citrullinated peptides has created a new path of research in rheumatology (van Venrooij and Pruijn, 2000). Historically, two autoantibodies namely the anti-perinuclear factor (APF) and the anti-keratin antibodies (AKA) are described to be specific for RA (Hoet and van Venrooij, 1992). Although the latter has lower specificity than the former, investigation on both antibodies shows that they are interrelated (Hoet *et al.*, 1991; Vincent *et al.*, 1999). They share the same antigen namely filaggrin in its matured form, which is citrulline-specific. Several years later, researchers find traces of other antibodies that also respond to citrulline-containing peptides, for example, anti-filaggrin in RA patients (Schellekens *et al.*, 1998). This becomes a foundation for further studies on the use of citrulline-containing peptides for RA diagnosis. Reactivity investigation of diverse citrullinated peptides shows a remarkable pattern of APF and AKA responses. Of all tested peptides, antibody responses towards cyclic citrullinated peptides (CCP) are remarkable in RA patients with 98% specificity. Nowadays, enzymatic assay against CCP is used as a common procedure in RA diagnosis (Aletaha *et al.*, 2010). The fact that the anti-citrullinated peptides antibodies (ACPA) can be detected before the first tissue damage makes them a reliable serological marker for early RA detection (Jansen *et al.*, 2002).

Citrullination in the RA Cycle

While the anti-citrullinated peptide antibodies (ACPA) acts as a potential serological marker for RA, it has been hypothesized that the citrullination pathway may participate in the RA cycle (van Venrooij and Pruijn, 2008). The citrullination process converts the peptidyl-bound arginine residue into a peptidyl-bound citrulline residue, as a result of posttranslational modification. The upregulation of citrullinated peptides is said to break the immune tolerance, triggering the release of the CCP-related antibodies and consequently the onset of RA. This creates a new level of understanding and opened opportunities for studies of the disease process.

In a review by Klareskog and colleagues, they summarize several factors including environmental, citrullination and genetic variants that contributed primarily towards the rise of ACPA (Klareskog *et al.*, 2011). The factors are interrelated, in which the disease could be triggered when multiple factors are present. Based on their early work, the research group discovered that the relation between smoking and RA could be seen via the presence of HLA-DR shared epitope (SE) genes in a particular person (Klareskog *et al.*, 2006). The probability of stimulating the disease is 21-fold higher in the smokers with the genes, when compared to those with the absence of either factor. As the enzyme that catalyzes citrullination, PAD, is also involved in apoptosis, it becomes activated. This indirectly increases the ACPA.

On a different note, there is a review on oral citrullination by a Gram-negative bacterium called *Porphyromonas gingivalis* (Mangat *et al.*, 2010). It is a major pathogen in periodontitis, an advanced gum disease that involves the inflammatory immune

response. Given the fact that *P. gingivalis* is the only bacteria to date to express PAD in its cells, it is speculated that the PAD expressed by the bacteria may have been able to catalyze the citrullination of human peptidylarginine too. Once the tolerance is broken, the immune responses are invoked. The bacteria association with RA is also supported by the level of antibodies to *P. gingivalis* in RA patient when compared to a healthy sample, indicating that the bacteria may have indeed plays a role in the disease development (Mikuls *et al.*, 2009).

Protein Arginine Deiminase IV (PAD4)

PAD4 belongs to the family of guanidinium modifying superfamily (GMSF). As the name suggests, these are proteins that are responsible in converting the guanidinium side chain into other functional groups. Together with PAD4, there are also PAD1, PAD2, PAD3 and PAD6 in the PAD family. As a matter of fact, it was thought that human PAD5 was a novel PAD. However, detailed investigations on the sequence and expression shows that the human PAD5 is analogous to the mouse PAD4. Therefore, it is renamed as PAD4, leaving a vacancy on the fifth type (Vossenaar *et al.*, 2003). PAD4 has several specific roles in normal body. It is involved in the formation of neutrophil extracellular traps (NET). The foundations of this NET are neutrophils, which are among the first responders during the occurrence of a bacterial infection. By the stimulation from PAD4, the neutrophils are combined to form a more complex NET system. This is proven by the disruption of NET when PAD4 is inhibited (Lewis *et al.*, 2015). Apart from that, PAD4 is also a corepressor of the p53 protein. This p53 is a tumor suppressor, which can initiate apoptosis of damaged deoxyribonucleic acid (DNA). By corepressing p53, PAD4 might induce the growth of the tumor, evidenced by the trace of PAD4 in patients with malignant tumors (Chang *et al.*, 2009). Other reviews on PAD4 and its roles can be found below (Fuhrmann *et al.*, 2015; Jones *et al.*, 2009).

PAD4 Structure

PAD4 contains 663 amino acids, with a molecular weight of 74 kDa. The first 294 amino acids are arranged in two immunoglobulin-like (I g) structures, making the N-terminal domain (Arita *et al.*, 2004). These subdomains are proposed to assist substrate selection and protein-protein interaction. Inside the subdomain 1, there is a nuclear localization signal (NLS) (56-PPAKKKST-63) that is arranged in a loop. This loop region is highly flexible as it exposed to solvent, which is explained by the high temperature factor in the crystallographic data. Based on the records, PAD4 is the only PAD with this NLS region. The peptide sequence acts as a tag that will interact with the nuclear transport receptors embedded in the nucleus envelope, for import into the cell nucleus.

The remaining sequence, is folded into a α/β propeller and forms the C-terminal domain. This domain ports all the active residues that are needed for the citrullination catalysis. The key residues are D350, H471, D473 and C645. PAD4 is only active in the presence of calcium and naturally exists as a homodimeric protein in solution. The dimer is reported to be in a head-to-tail fashion; that is between the N-terminal subdomain 1 of one monomer and catalytic domain of the other monomer. Fig. 2 illustrates the dimer structure of PAD4.

Calcium Dependency

It is common for proteins to have metal binding sites. A protein may contain one or more metal ions, which are unique in terms of their role and coordination. The basic functions of metals in proteins can be classified into five categories (Holm *et al.*, 1996): (1) For structural stability of the secondary or ternary protein structure, (2) for storage, (3) for electron transfer, (4) oxygen binding and lastly (5) for catalytic reaction. Data from crystallographic studies reveals that PAD4 had five unique calcium binding sites; three (Ca3–5) are in the N-terminal domain and another two (Ca1 and Ca2) are in the catalytic domain (Arita *et al.*, 2004). The recent 1.8 Å resolution structures of calcium-free and calcium-bound PAD4 (PDB ID: 1WD8 and 1WD9) reveals an interesting role of Ca1 and Ca2 towards the enzyme. The residues on the surface of PAD4 catalytic pocket is exposed to solvent in the calcium free PAD4. Upon the binding of the calcium, the residues are more structured. Further analysis of the electrostatic surface potential also indicates changes from the highly acidic to the more basic surface, where it is more favourable for peptidyl-arginine to bind. In addition, the geometry of the active site in the substrate-free, calcium bound PAD4 is found to be similar to that of the substrate bound PAD4, signifying that the formation of the active site is not dependent on substrate binding (Fig. 3). Overall, it is deduced that the catalytic pocket shape is highly dependent on these catalytic ions.

Liu and colleagues (Liu *et al.*, 2013) recently reported the role of calcium ions in the PAD4 N-terminal domain. Based on the kinetic studies, it is observed that the binding network of Ca3 and Ca4 is vital for full enzyme activation. Mutation of the residues that are coordinated with Ca3 and Ca4 namely D155, D157, and D179 diminishes the enzyme catalytic ability significantly. In contrast, the mutants with respect to the Ca5 binding show an indistinct effect on the catalytic efficiency, indicating that the enzyme has less dependency on the Ca5 binding.

Metal dependency of PAD4 has also been tested in a work reported by Kearney and co-workers (Kearney *et al.*, 2005). They concluded that only calcium can efficiently activate the PAD4 catalytic activity. Additionally, some of the metals even have the

Fig. 2 PAD4 dimer structure in head-to-tail fashion. Subdomain 1 is colored in yellow, subdomain 2 is in orange, and the catalytic domain is in deep teal.

Fig. 3 Superimposition of deep-teal colored calcium-unbound PAD4 (PDB ID: 1WD8) onto lemon color calcium-bound PAD4 (1WD9). Some parts of the proteins were set in higher transparency for visualization purpose.

ability to inhibit the protein and could possibly be a PAD4 deactivator. Metals that display strong PAD4 inhibition properties are manganese, samarium and zinc. These findings prove the importance of calcium in PAD4 activation. Interestingly, although the calcium ions are needed for citrullination catalysis, they do not affect the formation of the PAD4 dimer ([Arita et al., 2004](#); [Liu et al., 2011](#)).

Substrate Recognition

The PAD4 active site has a U-tunnel shape, with two door entrances (Fig. 4). The “front door” is the entrance where the actual substrate conversion takes place (Arita *et al.*, 2004, 2006). The “back door” on the other hand, is thought to provide access for solvent to enter and subsequently complete the hydrolysis (Linsky and Fast, 2010). The shape of tunnel is narrow, allowing only small molecules to enter and interact with the active residues. Similar two-door pockets have also been found in other guanidinium-modifying hydrolases, such as arginine deiminase (ADI) and dimethylarginine dimethylaminohydrolase (DDAH) (Linsky and Fast, 2010). An inspection on the structure of PAD4 complexed with benzoyl-arginine amide (BAA) substrate (Fig. 5) reveals several key residues that are important for substrate recognition. BAA is small substrate that mimics peptidylarginine and has been used widely as a positive control in any PAD4 related experiments. The guanidinium nitrogen atom of BAA is found to form double hydrogen bonds with the carbonyl side chain of D473 and D350. This secures the position of the guanidinium group for nucleophilic attack by C645. The opposite part of BAA is fastened by double and single hydrogen bonds from the R374 side chain and R639 backbone respectively. Another important residue is W347, which holds the part in between the substrate’s ends. The effect is best described as providing large hydrophobic effects to the substrates. Consistent with this interaction analysis, mutations of the above residues distract protein-ligand interactions significantly.

Fig. 4 Two-door pocket of PAD4 rendered using the crystal structure of PAD4 in bound with BAA (PDB ID: 1WDA). Some parts of protein are removed to ease visualization.

Fig. 5 Key residues in the PAD4-BAA interaction. Hydrogen bonds within 3.35 Å are presented in purple, when non-bonded contacts within the range of 2.90–3.90 are rendered in white.

Table 1 Sequences of designed peptides. The residues are presented in 1 letter amino acid code. C-terminal of each peptide was amidated

Peptide	Sequence
Pep1	MSPLRPQNY-NH ₂
Pep2	QLSLRTVSL-NH ₂
Pep3	PVVLRLKCG-NH ₂
Pep4	ISGKRSPAG-NH ₂
Pep5	KKSIRDTPA-NH ₂
Pep6	SSTPRSKGQ-NH ₂
Pep7	KNCFRMTDQ-NH ₂
Pep8	LWQWRKSL-NH ₂

The ability of PAD4 to convert free arginine remains a point of argument. PAD4 is indeed highly selective towards its substrates (Arita *et al.*, 2004). The enzyme recognizes oxygen atoms of BAA via R374 and R639. However, by using free arginine, the oxygen atom recognition by R374 cannot be established. This interrupts the interactions at R639, making free arginine a poor substrate.

Design of Peptide-Based PAD4 Inhibitors

There are several natural substrate of PAD4 such as histone, α -enolase, vimentin and nucleophosmin (Arita *et al.*, 2004; Hagiwara *et al.*, 2002; Suzuki *et al.*, 2007). To determine the peptide sequence that can bind strongly to PAD4, our group designed several peptides based on the sequence of nucleophosmin (Teo *et al.*, 2017). There are eight target residues i.e., arginine in the sequence of nucleophosmin so eight peptides were designed and named as Pep1 to Pep8. Pep1 to Pep7 consist of nine residues with four flanking residues before and after the target residue, arginine (region -4 to +4). While Pep8 consists of eight residues with only three flanking residues after arginine because it is near to the C-terminal of nucleophosmin. The sequence of each peptide is listed in Table 1.

The target amino acid of PAD4, arginine was positioned in the middle of the sequence and based on the sequence of nucleophosmin, four or three amino acids before and after arginine were chosen as the flanking residues that would aid in binding to residues around the active site of PAD4. The binding of each peptide to PAD4 was studied by comparing the rate of citrullination of each peptide to PAD4 small substrate, N- α -benzoyl arginine ethyl ester (BAEE). Peptides that bind well to the active site of PAD4 would be favourable in citrullination process and therefore more citrulline would be produced. To increase the affinity of the peptides in binding with PAD4, the best peptide was chosen for modification where the sequence was shortened from nine residues to 7, 5, and 3 residues.

The binding of the peptides after shortening were again compared to BAEE in order to identify the best sequence for PAD4 binding. The peptide having the greatest affinity to bind with PAD4 (with highest % relative activity) was selected for peptide-based inhibitor design. The target amino acid, arginine in the middle of the sequence was substituted with two amino acids: an amino acid with free amino side chain and L-2-furylalanine (Fig. 6).

Activity of Peptide-Based PAD4 Inhibitors

The relative activity of PAD4 with the designed peptides as substrate is shown in Fig. 7. Each peptide shows different substrate efficiency for citrullination by PAD4 demonstrating the influence of primary sequence of a peptide flanking an arginine. The influence of flanking residues in citrullination has also been reported in previous studies (Arita *et al.*, 2006; Hagiwara *et al.*, 2005; Nakayama-Hamada *et al.*, 2005; Takahara *et al.*, 1985; Tarcza *et al.*, 1996). However the amino acids could not be classified as favourable or unfavourable residues simply based on their physicochemical features. The influence of a residue on the citrullination by PAD4 is dependent on the overall sequence in which it is embedded (Stensland *et al.*, 2009).

Pep5 shows the highest activity to PAD4 with relative activity of 38%. It contains an aspartic acid at +1 position of arginine residue which results in a higher degree of citrullination (Stensland *et al.*, 2009). To improve the substrate efficiency for citrullination by PAD4, Pep5 was shortened from 9 residues to 7, 5 and 3 residues with the position of arginine remained at the middle of the peptides. The new peptides are named as Pep5_7, Pep5_5 and Pep5_3, respectively.

Fig. 8 shows the relative activity of PAD4 when the modified peptide served as substrate. When two amino acids are removed from each terminal in the sequence (Pep5_7), the relative activity of PAD4 increases drastically from less than 40% to nearly 100%. But when the number of residues is further reduced to five and three residues, the relative activity of PAD4 decreases. Pep5_5 and Pep5_3 may be too short in exhibiting sufficient interaction with PAD4 thus affected the substrate efficiency of the peptides on citrullination by the enzyme. This is in agreement with previous study where when long peptide was truncated, the peptides would be more unfavourable for citrullination (Stensland *et al.*, 2009).

Fig. 6 Chemical structures of amino acids substituted arginine in peptide-based inhibitors. (a) Amino acids with different side chain length ended with a free amino group, L-2,3-diaminopropionic acid (Dap), L-2,4-diaminobutyric acid (Dab), L-ornithine (Orn), and L-lysine (Lys). (b) L-2-furylalanine (Fal). (c) Branched peptide was formed by coupling free amino group of (a) with carboxylic group of (b).

Fig. 7 Screening of peptide substrates of PAD4. Eight designed peptides are utilized as substrates of PAD4 and the relative activity of PAD4 is calculated based on BAEE. Sequences of the peptides are shown in 1 letter amino acid code. The target arginine residue of PAD4 is shown in bold. C-termini of each peptide is amidated.

Fig. 8 Screening of shortened Pep5 as substrate of PAD4. Pep5 was shortened from 9 residues to 7, 5 and 3 residues and the modified peptides were utilized as substrate for PAD4. Sequences of the peptides are shown in 1 letter amino acid code. The target arginine residue of PAD4 is shown in bold. C-terminal of each peptide was amidated.

Among the designed peptides, Pep5_7 shows the highest relative activity on citrullination by PAD4 indicating that it has the most appropriate length and sequence to interact with PAD4. The peptide-based inhibitors are then designed according to the sequence of Pep5_7 (see Fig. 8). The arginine residue in the middle of the sequence was substituted with non-standard amino acid containing furan ring which was the common chemotype among the active compounds discovered by our previous works utilising structure-based and ligand-based drug design approaches (Teo *et al.*, 2012, 2013). Based on the findings from both approaches, peptide-based inhibitors were designed as branched peptides with the incorporation of furan ring in the structure. Branched peptide and peptidomimetic yielded from introduction of non-standard amino acid in peptide structure are better than an unmodified peptide in terms of biological activity, stability and specificity (Vlieghe *et al.*, 2010). They overcome the limitation of a peptide in acting as a drug with having better bioavailability. The general structure of the designed peptide-based inhibitors is shown in Fig. 9.

As the furan ring of Compound 5 discovered by ligand-based approach (Teo *et al.*, 2013) is able to enter the binding pocket of PAD4 and interacted with C645 i.e., an essential catalytic residue of PAD4 (Knuckley *et al.*, 2007) via hydrophobic interaction, our hypothesis is that the branch of the peptide would enter the binding pocket of PAD4 and interacts with the amino acids that are essential for the enzymatic activity. Inhibitors with different length of “neck” are designed by using four amino acids with different side chain length i.e., L-2, 3-diaminopropionic acid (Dap), L-2, 4-diaminobutyric acid (Dab), L-orthinine (Orn), and L-lysine (Lys) and named as Inh Dap, Inh Dab, Inh Orn and Inh Lys, respectively.

Most of the synthetic substrates and reported inhibitors of PAD4 (Jones *et al.*, 2012; Luo *et al.*, 2006a,b; Causey *et al.*, 2011) also having the “backbone”, “neck” and “warhead” parts in the structures (Fig. 10). Such design is inspired by the structure of a small synthetic substrate of PAD4, benzoyl-L-arginine amide (BAA). The fluoroacetamidine acts as the warhead to the active site of PAD4 in F-amidine. Luo *et al.* (2006a) then modified the warhead by changing fluoroacetamidine to chloroacetamidine. They discovered that chloroacetamidine is more potent than fluoroacetamidine in inhibiting PAD4. The second portion, which is the neck, consists of an alkyl skeleton and plays a role in strengthening the binding by interacting with residues lining the pocket. The length of side chain i.e., the “neck” was shown to be important in inactivation positioning (Luo *et al.*, 2006a). For their backbones, they are basically consist of a benzene ring and peptide bonds to mimic the structure of natural peptides. Modification of the backbone results in inhibitors with improved potency (Causey *et al.*, 2011).

Fig. 9 General structure of designed peptide-based inhibitors. The target residue, arginine was substituted with non-standard amino acid containing furan ring with different side chain length. C-termini of peptide-based inhibitors were amidated.

Fig. 10 The chemical structures of (a) designed peptide-based inhibitors, (b) BAA, and (c) F-amidine. All the structures are generally consisted of backbone, neck and warhead. Standard residues are shown in 1 letter amino acid code.

Table 2 IC_{50} values of the designed peptide-based inhibitors. IC_{50} values were calculated using GraphPad Prism 5.1

Inhibitors	$IC_{50} \pm SD$ (μM)
Inh Dap	243.2 ± 2.4
Inh Dab	315.5 ± 6.2
Inh Orn	> 2 mM
Inh Lys	277.3 ± 2.7

Inhibitory Activity of Peptide-Based Inhibitors

The inhibitory activity of the designed peptide-based inhibitors is investigated by calculating the IC_{50} value. Most of the inhibitors inhibit PAD4 significantly by reducing PAD4 activity to less than 50% at 2 mM except Inh Orn. The IC_{50} values of the peptide-based inhibitors are shown in **Table 2**. Among the inhibitors, Inh Dap is the most active inhibitor followed by Inh Lys and Inh Dab.

There is no direct relationship between the “neck” lengths of the inhibitor with the inhibitor potency. Luo *et al.* (2006a) have also studied the relationship between the “neck” lengths with the inhibitory ability of the amidine-based inhibitors. The length of the “neck” of the amidine inhibitors is varied by manipulating the methylene group from two to four units. Similar to peptide-based inhibitors, the inhibition potency is not directly related to the “neck” length of the compound where they found that amidines with three methylene units are more potent compared to that of two or four units. However this indicates that suitable “neck” length is crucial for proper position of the warhead in interacting with the active site of PAD4.

Inh Dap inhibits PAD4 the most among the inhibitors could be due to the suitable “neck” length. The relatively low IC_{50} values of peptide-based inhibitors compared to compounds discovered by structure-based and ligand-based virtual screening (Teo *et al.*, 2012, 2013) indicates that the incorporation of peptide with furan ring could be a better PAD4 inhibitor against PAD4 compare to conventional small molecule inhibitor.

Molecular Docking Analysis of Inh Dap

Molecular docking of Inh Dap against PAD4 is performed to investigate the interactions between the peptide with PAD4. The conformation of Inh Dap with the lowest energy calculated using NMR restrained MD simulations is selected for docking purpose. The binding affinity of Inh Dap to PAD4 is -5.4 kcal/mol, suggesting that the peptide has favourable interaction with PAD4. There are three hydrogen bonds formed between the inhibitor and the residues on the binding site of PAD4. The first one is established between the backbone carbonyl group of Thr6 and the side chain hydroxyl group of Ser468. The second is formed between the side chain carboxylic acid of Asp5 and the side chain amine of R374, while the third one is observed between the side chain amine of Dfa4 and the side chain carboxylic acid of D350. The binding of Inh Dap is mostly favoured by hydrophobic interactions between Dfa4 side chain that contains the furan ring and residues such as R639, W347, C645, H471, H640, E474, and D473. Other parts of Inh Dap such as Asp5 and Thr6 also make hydrophobic contacts with E575, R441, G403, V469, and G641 (**Fig. 11**).

It is interesting to highlight that the furan ring enters the deep binding pocket of PAD4 and made contacts with the residues that involved in the catalytic mechanism of PAD4, which are H471, D473, D350 and C645 (Kearney *et al.*, 2005). Similar interaction is also observed in the docked complex of PAD4-ligand discovered via ligand-based virtual screening (Teo *et al.*, 2013). Moreover, it is also worth to note that the presence of a hydrogen bond between Asp5 of Inh Dap with R374 of PAD4. As mentioned before, R374 is an important amino acid in the substrate recognition for PAD4 (Arita *et al.*, 2006). We anticipate that the contacts made between Inh Dap with C645 and R374 give the major contribution in inhibiting the PAD4 activity.

CD spectroscopy and NMR studies showing that Inh Dap is in unordered structure. A bent conformation is induced on Inh Dap upon binding to PAD4 (see **Fig. 12**). Previous studies reported that it is important for the peptide around the target residue to have a highly disordered conformation as PAD4 recognizes an unstructured peptide at the molecular surface near the binding site cleft and induces a bent conformation on the peptide (Arita *et al.*, 2006; Takahara *et al.*, 1985; Tarcsa *et al.*, 1996). The induction of the bent conformation is due to the hydrogen bonding between Inh Dap and Arg374 (Arita *et al.*, 2006). The bent shape allows the furan ring to enter the deep binding pocket of PAD4. The binding of furan ring in the active site cleft of PAD4 again confirms the importance of this structural fragment in the structure of PAD4 inhibitors.

Concluding Remarks

We show a systematic approach in designing a peptide inhibitor for PAD4. The unique architecture of PAD4 binding pocket requires the inhibitor to be able to penetrate deeply into the binding pocket while anchoring itself on the outer surface of the

Fig. 11 Binding conformation of *Inh Dap* inside the PAD4 binding pocket. (a) *Inh Dap* is seen occupying the binding pocket with the furan ring is located in proximity with C645 (yellow). Some of the protein parts were removed to ease visualization (Schrodinger, 2002). (b) Hydrogen bonds and hydrophobic interactions of *Inh Dap* with residues in the binding pocket of PAD4. The 2-dimensional binding diagram was created using Ligplot + version 1.4.5 (Laskowski and Swindells, 2011).

Fig. 12 Conformation of *Inh Dap* after binding to PAD4. A bent conformation was induced on *Inh Dap* upon its binding at the binding site of PAD4.

pocket. The screening of small molecules is carried out to choose the best “warhead” to attack the catalytic residues inside the binding pocket. The “warhead” is then attached to the carefully designed peptide with optimum neck and anchor lengths to ensure the peptide strongly binds to the neighboring residues while the “warhead” is attacking the catalytic residues. This approach in designing peptide inhibitor can be applied to similar cases where the catalytic residues are located far inside the binding pocket.

Introduction

For the balanced and proper functioning of all the life sustaining processes, nature has provided our body with all the necessary chemical components or precursors, enzymes and neurotransmitters. Despite this, due to several factors, some exogenous and some endogenous, some machineries or bioprocesses fail to function. The exogenous factors responsible for disrupting the normal bodily function may vary from parasitic invasion to some chemical entities. The endogenous factors include over or under-production of few chemicals, faulty functioning of organs or any genetic or congenital factor leading to disorders like neuro-degenerative disorders like Alzheimer's or Parkinson's disease resulting from the imbalance of acetylcholine and dopamine in the central nervous system (Moore *et al.*, 2005). Hence, to restore the normal functioning, external aids called 'Drugs' or 'Medicines' are required and the process of designing/discovery of drugs is called drug discovery. During this process, combinations of computational, translational, experimental and clinical models are employed to identify new potential therapeutic entities. In early days, most of the drugs were discovered either by the identification of the active ingredients from traditional remedies or by serendipitous discovery. Despite having knowledge of biological systems and advanced biotechnology, drug discovery and its development is still an expensive, time consuming, laborious, complicated and inefficient process with a high attrition rate of new therapeutic discovery. Hence, designing a drug or a molecule with desired properties and function is an important industrial challenge.

What is a Drug?

Drugs are biological or chemical entities of synthetic or natural origin, which modulate the functions of the body without causing any new action on the body. They can be a single compound or a mixture of different compounds. Drugs function by interacting and modifying specific 'targets' in our bodies to create a molecular interaction signature that can be exploited for rapid therapeutic repurposing and discovery. They interact and bind with the targets that are complementary to them in shape and charge and work either by stimulating or blocking activity of their targets. For example, the analgesic effect of drug Aspirin is due to inhibition of prostaglandin biosynthesis by acetylation of cyclo-oxygenase.

What is a Small-Molecule Drug?

According to National Cancer Institute, a small molecule drug is any organic compound or substance capable of entering cells with an ease due to its low molecular weight (below 900 Daltons). Once it enters the cells, it can affect other molecules, such as proteins, and may cause death of cancer cells. This is different from drugs, such as monoclonal antibodies, which are not able to enter the cells easily because of their large molecular weight. Therefore, most of the targeted therapies are small-molecule drugs or small molecule inhibitors.

Advantages of a Small-Molecule Drug

1. Small-molecule drugs are mostly administered orally which gives them an edge over larger drugs that require invasive procedures like injections.

The simple structures and smaller sizes of the small-molecule drugs facilitate more generic competition in comparison to complex biologic drugs. Owing to small molecular weight (i.e., less than 900 Daltons), they have easy penetration into cell membranes or target organs, thereby giving an intra-cellular targeting advantage over extracellularly oriented, specific biological proteins. Since small molecule drugs can be processed into easily ingestible tablets or capsule, they can be orally administrated. This increases the treatment regime, upregulates patient satisfaction and adherence and improves efficacy. Furthermore, these small molecule drugs have short half-life but longer shelf lives, which is of substantial therapeutic benefit especially in cases of rapid metabolism. Also, they require easy and less vigorous manufacturing processes as compared to complex biological drugs.

Characteristics of a Drug

A drug becomes active when it binds to its biological target, usually receptors. Receptors are protein having active sites for ligand binding. Hence, a good ligand can be designed, if the structure of such receptors and their active sites can be identified accurately. Before designing a drug, it is important to know what features we are looking for, in an "ideal drug candidate. The drug

- (i) Must be safe and effective.
- (ii) Should be well absorbed orally and have good bioavailability.
- (iii) Should be metabolically stable and have a long half-life.
- (iv) Nontoxic with minimal or no side effects.
- (v) Should have selective distribution to target tissues.

Drug Discovery

Drug discovery plays an important role to the society and for any pharmaceutical industry in 'improving the therapeutic value and safety of agents' by launching newer and safe drugs in the market. Unfortunately, the process of discovery and development of drug is a long and complicated process. It involves the identification, synthesis, characterization, screening and assays of potential candidates for therapeutic efficacy. Drug discovery and development process includes preclinical studies on cell-based and animal models followed by clinical trials on humans, and finally moving towards the step of obtaining regulatory approval to market the drug. Usually it takes at least 14–16 years of research with a cost of 800 million US dollars for a compound to get developed into a drug. After establishment of the pre-clinical data and confirmation of its action and toxicity, the compound is approved for clinical studies which takes 1–2 years before it is released into the market. After release, several post-market surveillance and pharmacovigilance practices are maintained to identify adverse reactions or incompatibilities when used in combination therapies (Congreve *et al.*, 2005). **Fig. 1** depicts entire drug discovery process with their tentative timelines.

Approaches for Drug Discovery/Designing

The traditional approach involves blind screening of chemical molecules obtained either from nature or synthesized in laboratories causing long design cycles and higher production cost. In modern drug discovery the identification of hits by screening, medicinal chemistry and optimization of these hits for enhances selectivity, metabolic stability and efficacy/potency, affinity and oral bioavailability. Enhanced electivity contributes towards reduction of potential side effects and metabolic stability increases half-life making the drug more stable. Drug discovery process can be made cost-effective and faster by using computer-aided drug design discovery process which involves structure-based drug design using in silico approach which plays a significant role in all stages of drug development. Since only a potential molecule is selected, this prevents late stage clinical failures thereby reducing the cost significantly. **Table 1** lists some inhibitors developed with computational chemistry and rational drug design strategies. Better understanding of the quantitative relationship of structure and biological activity reduces the development time of the drug to 6–8 years from 10 to 16 years. This supports the reasons to develop computer-aided molecular design (CAMD), towards automation of molecular design (Blaney, 1990; Bugg *et al.*, 1993). **Fig. 2** outlines the steps involved in the drug development process.

Various Approaches Involved in Drug Designing

Virtual screening

Virtual screening is a computational method used for identifying lead compounds using a vast and diverse chemical compound library as a reference. This computational method is an important tool for discovering lead compounds as it is faster, more cost-efficient, and less resource intensive in comparison to experimental methods such as high-throughput screening (Walters *et al.*, 1998; Shoichet, 2004; Kitchen *et al.*, 2004; Schneider and Bohm, 2002). Virtual screening process consists of two steps: docking and scoring. AutoDock (Morris *et al.*, 1998; Huey *et al.*, 2007) performs ligand conformational searches for identifying potential bound conformations, and X-Score (Wang *et al.*, 2002) is used in re-evaluating the binding affinity of the predicted structures. Novel lead compounds in many investigations have been successful identified using the freely available Autodock and X-score.

Docking and scoring

Docking is a computational way of predicting the most preferred orientation of one small molecule bound to a target, resulting into a stable complex. It consists of several steps. The first step is the application of docking algorithms that pose small molecules within the active site of the target. Through docking we aim to predict the stable drug interactions by inspecting and modelling drug molecular interactions between drug- and target receptor molecules. Various molecular docking tools are available, including AutoDock, FRED, eHITS, and FTDock, etc. (Maithri *et al.*, 2016). Scoring function is used for computing non-bonded interaction terms between the receptor and ligand atoms. Scoring functions approximate the receptor–ligand interaction energy using multivariate regression of multiple parameters such as the number of hydrogen bonds, lipophilicity, ionic interactions, entropy penalties, etc. Scoring functions are specifically designed to complement these docking algorithms as they evaluate the interactions between compounds and potential targets, thereby predicting their biological activity.

High-throughput screening (HTS)

In this technique, a large number of biological modulators and effectors are screened and assayed against selected and specific targets. The principles and methods of HTS can be exploited for screening of proteins, peptides, genomics and combinatorial

Fig. 1 Different phases of drug discovery process. Adapted and modified from Lombardino, J.G., Lowe, J.A., 2004. The role of the medicinal chemist in drug discovery—then and now. *Nature Reviews Drug Discovery* 3, 853–862.

chemistry libraries. HTS is a high-tech way to hasten the drug discovery process, allowing quick and efficient screening of large compound libraries at a rate of a few thousand compounds per day or per week. (Martis *et al.*, 2011).

Homology modelling

Computational methods can be used to predict the 3D structure of target proteins when experimental structures are not present. Since proteins with similar sequence have similar structures, comparative modelling is used to predict target structures based on a template with similar sequences. Homology modelling is a specific kind of comparative modelling in which the same evolutionary origin is shared by template and target proteins. Some computer programmes and web servers which are commonly used for automated homology modelling process are PSI-PRED and MODELER (Buchan *et al.*, 2010; Martí-Renom *et al.*, 2000).

Molecular dynamic simulations

Owing to the dynamic nature of biomolecules, a single static structure cannot be applied to predict putative binding sites. An assembly of target conformations starting from a single structure are obtained by applying classic molecular dynamic (MD) simulations. In MD methods principles of Newtonian mechanics are employed to calculate trajectory of conformations of a protein as a function of time. The problem with classic MD method is that it gets trapped in local energy minima. To overcome this problem, various advanced MD algorithms such as conformational folding simulations (Grubmüller, 1995), targeted-MD (Schlitter *et al.*, 1994), replica exchange MD (Sugita and Okamoto, 1999) and temperature accelerated MD simulations (Abrams and Vanden-Eijnden, 2010) have been employed for traversing multiple minima energy surface of proteins.

Monte Carlo simulation

The Monte Carlo simulation is based on the concept of statistical mechanics. Monte Carlo introduces a randomness in the system that allows hopping over the energy barriers thereby preventing the system from getting stuck in the local energy minima

Table 1 Selected inhibitors developed with computational chemistry and rational drug design strategies

Compound name	Structure of the compound	Therapeutic area	Function	Approval
Captopril		Hypertension congestive heart failure myocardial infarction diabetic nephropathy	ACE inhibitor	1975
Cimetidine		Treatment of heartburn and peptic ulcers	H2-receptor antagonist	1978
Dorzolamide		Antiglaucoma agent	Antiglaucoma agent carbonic anhydrase inhibitor	1989
Imatinib		Chronic myeloid leukemia	Tyrosine kinase inhibitor	1990
Saquinavir		Antiretroviral drug used to treat or prevent HIV/AIDS (1st generation)	HIV-1 protease inhibitor	1995
Oseltamivir		Antiviral (to treat influenza A and influenza B)	Influenza neuraminidase inhibitor	1996

(Continued)

Table 1 Continued

Compound name	Structure of the compound	Therapeutic area	Function	Approval
Indinavir		Antiretroviral drug used to treat HIV/AIDS (1st generation)	HIV protease inhibitor	1996
Ritonavir		Antiretroviral drug used to treat HIV/AIDS (1st generation)	HIV protease inhibitor	1996
Zanamivir		Antiviral (to treat influenza A and influenza B)	Neuraminidase inhibitor	1999
Nelfinavir		Antiretroviral drug used to treat HIV/AIDS (1st generation)	HIV protease inhibitor	1999

(Continued)

Table 1 Continued

Compound name	Structure of the compound	Therapeutic area	Function	Approval
Lopinavir		Antiretroviral drug used to treat HIV/AIDS against strains that are resistant to other protease inhibitors (1st generation)	Peptidomimetic HIV protease inhibitor	2000
Fosamprenavir		Antiretroviral prodrug used to treat HIV/AIDS (phosphorester that is rapidly and extensively metabolized to amprenavir) (1st generation)	HIV protease inhibitor	2003
Gefitinib		NSCLC	EGFR kinase inhibitor	2003
Atazanavir		Antiretroviral drug used to treat HIV/AIDS (2nd generation)	HIV protease inhibitor	2004

(Continued)

Table 1 Continued

Compound name	Structure of the compound	Therapeutic area	Function	Approval
Tipranavir		Antiretroviral drug used to treat HIV/AIDS (tipranavir is active against strains that are resistant to other protease inhibitors) (2nd generation)	Nonpeptidic HIV-1 protease inhibitor	2005
Erlotinib		NSCLC pancreatic cancer	EGFR kinase inhibitor	2005
Sorafenib		Renal cancer Liver cancer thyroid cancer	VEGFR kinase inhibitor	2005
Darunavir		Antiretroviral drug used to treat HIV/AIDS (2nd generation)	Nonpeptidic HIV-1 protease inhibitor	2006
Lapatinib		ERBB2-positive breast cancer	EGFR/ERBB2 inhibitor	2007

(Allen and Tildesley, 1989). In protein dynamics, Monte Carlo simulation run is a sequence of random steps in conformation space inside a box where the step is decided on the basis of changes in the values of energy function during a simulation.

Metropolis criterion (MCM) simulations

Since MCM requires only energy function for evaluation and not the derivate of energy function unlike traditional MD which drives a system towards local energy minimum, conformational space is sampled faster with MCM than molecular dynamics. For flexible docking applications such as MCDOCK, MCM simulations have been adopted (Liu and Wang, 1999).

Rational drug design

Rational drug designing is based on the principle of logical reasoning before designing any therapeutic agents. For example, to prepare a competitive inhibitor relative to any specific target, the predicted structure should ensure that the designed molecule exhibits endogenous properties. The active site should be closely examined to get idea regarding the interacting amino acid residues, so that the nature and type of substituents and the favourable position in the molecule can be predicted, resulting in better binding.

Genetic algorithms

Genetic algorithms recombine parent conformations to child conformations which provides for molecular flexibility. The best scoring or “fittest” combinations are kept for another round of recombination during this evolutionary simulation process. Best possible set of solutions are evolved in the process retain favourable features from one generation to the next. Rational drug design does not involve exhaustive searches that involve impractical large combinatorial problems. The investigation of such problems is greatly aided by genetic algorithms; a class of algorithms mimicking some of the major characteristics of Darwinian evolution. In order to design small organic molecule with satisfying quantitative structure-activity relationship based rules (fitness), a specific

algorithm called an LEA (Ligand by Evolutionary Algorithm) has been conceived. The fitness consists of a sum of constraints that act as range properties. The LEA takes an initial set of fragments and repeatedly improves them by means of mutation and crossover operators which are related to those involved in the Darwinian model of evolution (Dougueta et al., 2000).

Molecular fingerprint and similarity searches

Molecular fingerprinting is a way of representing molecules which can be exploited to identify and compare structurally similar molecules or to cluster them on the basis of structural similarity. This method is based on fewer hypotheses and is less computationally taxing than QSAR or pharmacophore mapping models and is more quantitative in nature since it relies entirely on chemical structure and omits compounds with known biological activity. Moreover, fingerprint-based methods equally consider all parts of the molecule instead of focusing on only those parts of the molecule which are thought to be most important for activity. Hence, this method is less prone to error overfitting and requires smaller datasets to begin with. Fingerprint methods can also be used for searching databases for compounds that are similar in structure to a lead query, thereby providing an extended collection of compounds that can be tested for improved activity over the lead.

De Novo ligand designing

Constructing novel molecules from scratch is called de novo drug design. This approach is particularly challenging because the compound space to be searched can often become enormous. Defining a binding site for molecules in a target and determining what atoms or functional groups should be placed at certain loci at the binding site is one of the most critical and difficult steps of de novo drug design. (Klebe, 2000; Bohm and Stahl, 2000).

Case Studies

Discovery of tyrosine kinase inhibitors by docking into a molecular dynamics generated inactive kinase conformation

Type II inhibitors, which are the inactive DFG-out conformation of tyrosine kinases show good binding and selective profiles with several small molecules over other kinase targets. An explicit solvent molecular dynamics (MD) simulation of the complex of the catalytic domain of a tyrosine kinase receptor, ephrin type-A receptor 3 (EphA3), and manual docking of type II inhibitors was performed to obtain a set of DFG-out structures by Zhao et al. (2012). A single snapshot from the MD trajectory (for virtual screening) was selected using the automatic docking of four previously reported type II inhibitors (Fig. 3). Since a glycine-rich loop (Gloop), can adopt various conformations, it tightly encompasses the small type I head group of compound 1 and collapses into the ATP binding site. As a result, the bigger type I head groups of compounds 2–4 clashes with the G-loop in the ATP binding site. In addition, the entry of the piperazine group of compound 4 is blocked by the side chain of Tyr742 (Fig. 4). High-throughput docking of a pharmacophore-tailored library of 175,000 molecules results in about 4 million poses, which can be further filtered and sorted by van der Waals efficiency and force-field-based energy function. Remarkably, about 20% of the compounds with predicted binding energy smaller than $-10 \text{ kcal mol}^{-1}$ are known to be type II inhibitors and besides, a series of 5-(piperazine-1-yl)isoquinoline derivatives was identified as a novel class of low-micromolar inhibitors of both EphA3 and dephosphorylated Abelson tyrosine kinase (Abl1). A similar affinity to the gatekeeper mutant T315I of Abl1 is suggested by the in silico binding mode of the new inhibitors and competition binding assay studies. Additional evidence for the type II binding mode was obtained by two 300 ns MD simulations of the complex between N-(3-chloro-4-(difluoromethoxy)-phenyl)-2-(4-(8-nitroisoquinolin-5-yl)piperazin-1-yl)acetamide and EphA3 provided additional evidence of the type II binding mode.

Most type II inhibitors can be mapped well into three major hydrophobic interactions: ATP front site, ATP back site, and the allosteric site (Fig. 5).

Computer-Aided Drug Design (CADD)

CADD helps scientists in minimizing the synthetic and biological testing efforts by focussing only on the most promising compounds. Besides explaining the molecular basis of therapeutic activity, it also predicts possible derivatives that would improve activity. CADD entails (Kapetanovic, 2008):

- (1) Drug discovery and development processes being streamlined by the use of computing power.
- (2) Identification and optimization of new drugs using leverage of chemical and biological information about targets and/or ligands.
- (3) In silico designing of filters for the elimination of undesirable compounds with properties like poor activity and/or poor absorption, distribution, metabolism, excretion and toxicity, ADMET which facilitate selection of the most promising candidates.

Advantages of CADD

The main advantages of drug discovery through CADD are:

- (i) For experimental testing, smaller set of compounds are selected from large compound libraries.

Fig. 3 Known type II inhibitors of EphA3. The values next to the compound number are the experimentally measured dissociation constant against phosphorylated EphA3 and the predicted binding free energy. These values were calculated by using the MD-IF structure and a scoring function with continuum solvation and hydrogen bonding penalty.

- (ii) Drug metabolism and pharmacokinetics (DMPK) properties like absorption, distribution, metabolism, excretion and the potential for toxicity (ADMET) are increased by optimization of lead compounds.
- (iii) Designing of novel compounds can be achieved either by “growing” starting molecules one functional group at a time or by piecing together fragments into novel chemotypes (Veselovsky and Ivanov, 2003).
- (iv) Traditional experimentation which requires animal and human models can be replaced by CADD, saving both time and cost (Mallipeddi *et al.*, 2014).

Fig. 4 Comparison of A) the crystal structure (PDB: 3DZQ) of the complex of EphA3 with inhibitor 1 and B) the binding mode obtained by docking compound 4 into the MD-IF structure. For the differences in orientations of Tyr 742 and Phe 765, and in the G-loop. Adapted and modified from Zhao, H., Huang, D., Caffisch, A., 2012. Discovery of tyrosine kinase inhibitors by docking into an inactive kinase conformation generated by molecular dynamics. *ChemMedChem* 7 (11), 1983–1990.

Fig. 5 Key interactions pharmacophore mapping of type II kinase inhibitors illustrated by compound 2 and EphA3. Dashed lines are hydrogen bonds. Pharmacophore elements used to filter the ZINC library: two acceptors (dashed circles), one donor (solid circle), and three hydrophobic rings (ovals). Because of the flexibility and solvent exposure of the Glu 670 side chain, the hydrogen bond to Glu 670 was not used as a pharmacophore.

- (v) Reduces the chances of drug resistance and thus would lead to production of lead compounds which would target the causative factor.
- (vi) CADD also leads to the construction of high quality datasets and libraries that can be optimized for high molecular diversity or similarity (Ou-Yang *et al.*, 2012).

Types of CADD

The choice of CADD approaches to be employed is determined by the availability of the experimentally determined 3D structures of target proteins. Structure-based CADD uses our knowledge of the target protein structure to calculate interaction energies,

whereas in ligand-based CADD, chemical similarity searches or construction of predictive, quantitative structure-activity relationship (QSAR) models exploits our knowledge of known active and inactive molecules. (Kalyanamoorthy and Chen, 2011). Structure based CADD combines information from several fields, for example, X-ray crystallography and/or NMR, synthetic organic chemistry, molecular modelling, QSAR, and biological evaluation (Marrone *et al.*, 1997). Through structure based CADD, we aim to design compounds with strong binding affinity with the target, thereby exhibiting properties like reduced free energy, improved DMPK/ADMET properties and target specification i.e., reduced off-target (Jorgensen *et al.*, 2010). Virtual high-throughput screening (vHTS) also known as screening of virtual compound libraries is one of the most common applications of CADD (Kalyanamoorthy and Chen, 2011). Fig. 6 represents an overview of CADD drug designing/design pipeline.

Structure-based drug discovery

This method exploits knowledge of the three-dimensional structure of a receptor complexed with a lead molecule for optimization of the bound ligand or a series of congeneric molecules. It requires the understanding of receptor-ligand interactions. The structural information can be obtained either from X-ray crystallography, NMR, or from homology modelling. A medicinal chemist can use a model with a given structure for computing the activity of a molecule (Lewis, 2005). Some of these approaches provide accurate binding modes, while cater to fast searching of large databases. Some approaches of structure-based drug designing are explained below.

Structure-based virtual high-throughput screening

Structure-based virtual high-throughput screening (SB-vHTS) is an *in-silico* method which helps identify putative hits out of hundreds of thousands of compounds to the targets of known structure. It is usually based on molecular docking. In molecular docking, a small molecule is fitted into the active site of protein model and here, comparison of the 3D structure of small molecule with the putative binding pocket is carried out. In the traditional HTS, the general ability of a ligand to bind, inhibit or allosterically alter the proteins function is asserted experimentally, whereas in SB-vHTS selects the ligands that are predicted to bind to a specific binding site. To ensure the feasibility of screening of large compound libraries within a finite time, limited conformational sampling of proteins and ligands is used by SB-vHTS along with a simplified approximation of binding energy that can be computed rapidly (Becker *et al.*, 2006).

Structure-based virtual screening

This is a computational approach for identifying potential drug candidates (hits) that are capable of binding to a drug target (protein receptors, enzymes). This method involves quick searching of large libraries of chemical followed by docking of the hit into a protein target and finally application of a scoring function for estimating the probability of binding affinity of drug candidate with the protein target (Cheng *et al.*, 2012). The most important advantage of this screening is that it enhances the hit rate by considerably decreasing the number of compounds that are estimated experimentally for their activity and hence improves

Fig. 6 An overview of CADD drug designing/design pipeline. Adapted and modified from Guido, R.V., Glaucius Oliva, G., Andricopulo, A.D., 2008. Virtual screening and its integration with modern drug design technologies. Current Medicinal Chemistry 15, 37–46.

the success rate of the *in vitro* experiments. This method has been applied extensively in pharmaceutical companies and academic groups for early-stage drug discovery.

Fragment-based lead discovery

This approach is based upon structure-activity relationships (SAR), obtained from NMR for identifying and optimizing the lead (Bienstock, 2011). High purity, weak potency but effective binding, good aqueous solubility, (molecular weight < 300, ClogP < 3, number of rotatable bonds, number of hydrogen bond donors and acceptors each should be < 3) are the criteria for selecting the chemical fragments (Congreve *et al.*, 2003). Later, these fragments are either expanded or combined for producing a lead with a higher affinity.

In silico structure-based lead optimization

After the desired hits are identified through virtual screening, this method speeds up the search for optimized lead by delineating the prediction about its pharmacological properties, thereby reducing the *in vitro* and *in vivo* experimental time.

ADMET modelling

This method, a common name for which is physiologically-based pharmacokinetic modelling is used in drug design and development, and in assessing of toxicity threat evaluation and specifically predicts absorption, distribution, metabolism, excretion and toxicology (ADMET) of drugs/compounds in humans. The ADMET parameters are based on the kinetics of the drug exposure to tissues and how the body will react to them, influencing the performance and pharmacological activity of the compound. Therefore, this method provides a key insight into the behaviour of a pharmaceutical compound within an organism. This approach aids in the selection of compounds during the very early phases of drug thereby playing a crucial role in drug discovery and development. This technique is cost- and time effective owing to a reduction in attrition of drugs during the pre-clinical / clinical phase trials at a later stage.

Ligand-based drug designing

The existing knowledge of active compounds against the target is used to predict new chemical entities that present similar behaviour in Ligand-based methods (Martin *et al.*, 2002). Given a single known active molecule, a pharmacophore model can be derived from a library of molecules to define the minimum necessary structural characteristics a molecule must possess in order to bind to the target of interest. A fingerprint-based similarity search is usually used to compare the active molecule to the library as here, the molecules are represented as bit strings which represent the presence or absence of predefined structural descriptors (Mishra and Siva-Prasad, 2011). In comparison, targeting structural information to determine whether a new compound is likely to bind and interact with a receptor is the method that structure-based methods rely on. No prior knowledge of active ligands is required in this method, which is a significant advantage (Kolb *et al.*, 2009). It is possible to design new ligands that can elicit a therapeutic effect from 3D structures. Therefore, the development of new drugs through the discovery and optimization of the initial lead compound are greatly impacted by structure-based approaches.

Ligand-based virtual screening (LBVS)

Ligand-based virtual screening is based on the "similarity principle" according to which similar molecules tend to exhibit similar biological properties. Scaffold hopping i.e., identification of iso-functional molecular structures with significantly different molecular backbones is the usual objective when using LBVS. "Scaffold hopping" is also known as "leapfrogging", "scaffold searching" and "leap hopping" (Kalliokoki, 2010). These methods are usually helpful in drug repurposing, wherein new targets and diseases are pursued for existing drug molecules.

Molecular descriptors

This is one of the simplest approaches in which the reference molecule/set of molecules are compared with a large library of compounds at a very low cost on the basis of physicochemical properties descriptors, such as molecular weight, volume, geometry, surface areas, atom types, dipole moment, polarizability, molar refractivity, octanol-water partition coefficient (log P), planar structures, electronegativity, or solvation properties that are obtained from experimental measurements or theoretical models. Molecules are represented by symbols for effective execution of the task (Prada-Graciaa *et al.*, 2016).

Quantitative structure-activity relationship models (QSAR)

The mathematical relation between structural attributes and target response for a set of chemicals are explained by Quantitative Structure-Activity Relationship models. Structural and/or property descriptors of compounds can also be correlated with their biological activities using QSAR (Bernard *et al.*, 2005). Through QSAR models we can correlate various features like rate constants, binding sites affinities of ligands, inhibition constants and other biological activities, either with certain structural features (Free Wilson analysis) or with atomic, molecular or group properties, such as lipophilicity, electronic, steric and polarizability, among congeneric series of compounds. (Kubinyi, 1995). Hence, the success of QSAR is dependent on the choice of descriptors and the ability to generate the appropriate mathematical relationship besides the quality of initial set of active/inactive compounds.

Pharmacophore modelling

More significant information can be drawn by employing various conformations of a range of ligands than just a single ligand structure. A pharmacophore model of the receptor site can be generated with a sufficiently broad range of ligands. Pharmacophore

Homology modeling of DFG-in FMS-like tyrosine kinase 3 (FLT3) and structure-based virtual screening for inhibitor identification. Scientific Reports 5, 11702. Doi: 10.1038/srep11702.

modelling of smaller, non-peptide molecules that might have improved stability and bioavailability over their peptide counterparts has resulted in successful outcomes so far (Nielsen *et al.*, 1999).

Case Studies

Computer aided drug designing (CADD) for EGFR protein controlling lung cancer

Epidermal growth factor receptor (EGFR), a receptor tyrosine kinase plays an important role in tumour cell survival. Phosphorylated EGFR upon activation causes phosphorylation of downstream proteins that lead to changes in cell proliferation, invasion, metastasis, and inhibition of apoptosis. Human EGFR was taken as a protein by Baskaran *et al.* (2012), and commercially available drugs (such as Gemzar, Gefitinib, Tarceva) were taken as ligands. The drugs were docked to this receptor and Gefitinib and Tarceva were chosen based on the energy values. To improve the binding efficiency and steric compatibility of these two drugs, modifications were made to the probable functional groups which were interacting with the receptor molecule. Analogs were prepared using ACD Chem Sketch in MOL format which were then converted to 3D structure using Weblab Viewer Lite, a 3D modelling program. It was then docked using Vega ZZ docking software. Gefitinib Analog 2(281) and Tarceva Analog 7 had significantly lower energy values and were found to be better than the conventional drugs available (Fig. 7).

Structure-based virtual screening (SBVS), for the identification of new chemotypes for FLT3 inhibition

FMS-like tyrosine kinase 3 (FLT3) is a type III tyrosine kinase receptor and is highly expressed in hematopoietic stem and progenitor cells. FLT3 binds to extracellular domain which activates cytoplasmic tyrosine kinase activity leading to activation of

Fig. 9 Computer-aided drug design (CADD) strategy for FLT3 inhibitor identification. Adapted and modified from Ke, Y.Y., Singh, V.K., Coumar, M.S., *et al.*, 2015. Homology modeling of DFG-in FMS-like tyrosine kinase 3 (FLT3) and structure-based virtual screening for inhibitor identification. Scientific Reports 5, 11702. Doi: 10.1038/srep11702.

downstream cellular signalling which is essential for proliferation. Based on the position of the Phe residue of the DFG motif, the inhibitors are named Type I or Type II inhibitors. In a DFG-in conformation, the Phe residue is oriented outside the ATP binding site while in a DFG-out conformation; the Phe residue is oriented inside the ATP binding site. Inhibitors that bind to the DFG-in conformation are termed type-I inhibitors, and those that bind to the DFG-out conformation are referred to as type-II inhibitors. In Fig. 8, Ke *et al.* (2015), superimposed the FLT3-modeled (DFG-in) structure on the 1RJB (DFG-out) template structure to depict the structural differences between the DFG-in and DFG-out conformations. Since type-I inhibitors bind strongly to FLT3-ITD-mutated kinase, they are proven to be more effective against treatment of acute myeloid leukemia.

Homology modelling (HM) of the DFG-in FLT3 structure identifies known DFG-in (SU11248, CEP-701, and PKC-412) and DFG-out (Sorafenib, ABT-869 and AC220) FLT3 inhibitors using docking studies (citation of the study). SBVS of an HTS library of 125,000 compounds was done with the modeled structure. Out of the 97 top scoring compounds, two hits (BPR056, $IC_{50}=2.3$ and BPR080, $IC_{50}=10.7 \mu M$) were identified. Based on molecular dynamics simulation and density functional theory calculations BPR056 (MW: 325.32; cLogP: 2.48) was identified to interact with FLT3 in a stable manner and was studied to be chemically optimizable to realize a drug-like lead in the future. The overall CADD strategy used in this study is shown in Fig. 9.

This superimposition reveals that the activation loop in the DFG-in structure flipped away from the active site which leads to the placement of the Phe830 group away from this site. In the DFG-out structure, the activation loop overturned towards the active site, resulting in the placement of Phe830 in the active site. The different arrangements of the activation loop, particularly in regards to the placement of the Phe830 group, have profound implications for the binding of different types of inhibitors to FLT3 kinase.

More than 40% inhibition at a $10 \mu M$ concentration was observed for BPR056 and BPR080, out of 97 screened compounds (Table 2).

In order to design better FLT3 inhibitors it is important to understand the binding modes of these two high scoring poses in the modeled structure. Both the molecules were observed to bind at the ATP binding site by forming Hydrogen bonds with the

Table 2 FLT3 kinase inhibition profiles, docking score and binding energies of the hits identified from the in-house HTS database. PKC412 and sorafenib are used as reference compounds for the comparison

Compound	FLT3 IC_{50} (nM)	Docking score Predicted binding energy (kcal/mol)			
		DFG-in	DFG-out	DFG-in	DFG-out
 BPR056	2300	-355	-276	-23.04	16.41
 BPR080	10,700	-350	-314	-22.92	19.82
Midostaurin (PKC412)	37	-269	-165	-34.21	19.13
Sorafenib (BAY43-9006)	102	-183	-300	-7.06	-12.32

Adapted and modified from Ke, Y.Y., Singh, V.K., Coumar, M.S., *et al.*, 2015. Homology modeling of DFG-in FMS-like tyrosine kinase 3 (FLT3) and structure-based virtual screening for inhibitor identification. Scientific Reports 5, 11702. Doi: 10.1038/srep11702.

hinge-region Cys694 residue. A hinge-region H-bond interaction between an inhibitor and kinase is an essential component in inhibitory activity and are common in several inhibitor–kinase complex structures.

DFG and FLT3 inhibitor complex was subjected to 20 ns using the Gromacs MD suite. The root mean square deviation showed that the both cases found to be at equilibrium from initial position and remained stable after 10 ns. In addition RMSF values of complex were also determined and it showed that the major differences occurs between the both complexes occurred in the loop region and more fluctuations in the FLT3-BPR080 interacting complex (Ke *et al.*, 2015). Detailed docking, DFT calculations and 20-ns MD simulations of the new hits in the DFG-in FLT3-modeled structure suggest that the interaction between BPR056 (MW: 325.32; cLogP: 2.48) and FLT3 is stable and could, in the future, be chemically optimized to realize a drug-like lead.

Fragment-based drug design to target the EphA4 kinase domain

The first approved drug that was developed via fragment-based approach is Vemurafenib (4, Fig. 10), a kinase inhibitor of the B-Raf V600E oncogenic mutant. High content screening (HCS), a type of phenotypical screening, followed by X-ray crystallography yielded an unselective 7-Azaindole fragment (Figure 12) as hit fragment, which was optimized via 2 into the selective B-Raf inhibitor PLX472077 (3) to end up with Vemurafenib (PLX4032, 4) (Bollag *et al.*, 2010).

Limitations of CADD

Despite the emergence of the numerous above-mentioned pioneering approaches, drug design and development is still an inherently risky business where the input costs are high and the success rate is low. Generally, only one in 1000 lead compounds reaches phase 1 clinical trials and only one in five drugs make it from phase 1 trials into the marketplace (Wishart, 2006). Some procedures concerning Computer Aided Drug Designing are time consuming, especially while looking for a proper lead component (Jorgensen, 2004). The current molecular docking algorithms do not estimate the absolute energy associated with the intermolecular interaction with satisfactory accuracy as most of the available scoring functions are classical approximations of events ruled by quantum mechanics. Further, there is lack of accurate experimental data that restricts further advancement of CADD (Bharath *et al.*, 2011). Hence, new experimental or computational tools and scientific approaches to identify correlations between the nature and structure-based properties of the drug and of its safety and efficacy in the human body (pharmacovigilance-based) are in vital need of improvement so

Fig. 10 Optimization of the non-selective 7-Azaindole fragment (24) into Vemurafenib (PLX4032, 27).

potentially problematic drug leads could be identified at the early stages in their development. This will improve the public health and provide a safe, effective and rational use of medicines and their development.

Conclusion & Future Perspectives

CADD has now become an indispensable tool in the long process of drug discovery and development. It also provides options for understanding chemical systems in different ways, yielding information that is not easy to obtain in laboratory analysis, with considerably less cost and effort than experiments. Initially, CADD had a rocky perception in the field of drug development, and perhaps some over-hyping of its promises, as is present in the initial stages of almost any new technology or development. Today, one can say that the discipline of computational medicinal chemistry has begun to mature and is a routinely used component of modern drug discovery process. Mastering different kinds of CADD approaches and their software and utilizing all computational resources that are valuable for drug design are certainly essential for becoming a successful computational medicinal chemist in today's world. In addition, having skills in one or more programming languages, such as Python or JAVA will help smooth routine drug-design work. SBVs and LBVs are also very likely to become routine in drug-discovery projects if they are not considered to have already done so. The use of more accurate methods like MD and QM, continue to grow. In conclusion, CADD is beneficial for pharmaceutical development in the areas of prediction of 3D structures, design of compounds, prediction of druggability, in silico ADMET prediction however, it must be realised that computational predictions need to be integrated with experimental approaches for successful drug discovery and development.

Introduction

Computational docking simulation is no longer an unfamiliar step in drug discovery since the last few decades. As time and financial costs are crucial factors in drug discovery and development, it is important to constantly reform the drug discovery pipeline with novel technologies such as virtual screening or docking that can narrow down the candidates to the most promising lead compound for further testing. This *in silico* approach has been widely applied in the preliminary stage as well as to probe the insight into the molecular mechanism of the protein-ligand interaction in drug discovery life cycle. The past decade has witnessed tremendous growth in computational capabilities that enable computational docking to expedite the discovery of many potential inhibitors. Here, we review its potential application in the discovery of potential inhibitors to one of the deadly infectious diseases, namely the Dengue infection.

Background

Dengue is a growing global health concern with an estimated 390 million infections occurring each year (Bhatt *et al.*, 2013). It is caused by the Dengue virus (DENV), a flavivirus (*Flaviviridae*) that is transmitted by *Aedes aegypti* and *Aedes albopictus* mosquitoes. The infections are endemic in tropical and subtropical regions but are spreading to higher latitudes in recent times. To date, there are still no approved antivirals to stop dengue and currently, patients are only treated with supportive care to relieve fever, pain and dehydration. On the other hand, there have been a few vaccine candidates in advanced clinical pipeline. However, the development of an efficacious and safe vaccine for dengue is not without challenges as the virus has at least four serotypes. A major hurdle is the requirement for a working vaccine to be “tetraivalent” that is immunogenically effective against all the four serotypes. If protection against one or more serotypes is insufficient, the “vaccinated” person may develop a more severe disease due to the mechanism called antibody-dependent enhancement (Halstead, 2014). Recent discovery of the fifth serotype of the DENV (Vasilakis *et al.*, 2013) further complicates the vaccine development effort.

Alternatively, the development of dengue antiviral small molecule seems viable as the structures of the proteins, the parts which make up the virus particle are largely well characterised (Kuhn *et al.*, 2002; Smit *et al.*, 2011). These DENV components are divided into “structural” proteins (capsid, envelope protein and M protein) that construct the virus and seven “non-structural” proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5) that play functional and enzymatic roles (Fig. 1). Knowledge and understanding of their structural features and roles in virus infection has grown tremendously. “Structural” proteins despite their names, have been shown to play active roles in the life cycle and propagation of the DENV. For example, the DENV envelope (E) protein, has been shown to play crucial roles in the attachment and entry of the virus into the host cells, the key steps in the infection (Rey, 2003; Modis *et al.*, 2004).

It is not surprising that anti-flaviviral discovery efforts in the recent decade (2006–2016) have focused on these viral proteins as targets for new small molecule inhibitors. In these target-oriented efforts, computational or *in silico* methods have played increasingly important roles in the discovery process. The availability of high resolution DENV proteins’ crystal structures in the Protein Database (PDB) (Berman *et al.*, 2003) partly encourages this trend where docking technique, in particular, has been employed as a tool to virtually screen large libraries of compounds against the protein crystal structures. To a lesser extent, docking procedures have also been used to model the inhibitory activity of a promising lead and help rationalise its mechanism of action towards improving the ligand’s potency.

This review aims to highlight recent (2006–2016) efforts in which *in silico* docking played important roles in the discovery of new DENV inhibitors. Whenever possible, we attempt to keep the review to projects where the docking results are followed through or validated with experimental data. We discuss the outcomes of these projects and evaluate their prospects, and finally identify least explored areas or targets which may hold promise for future *in silico* discovery of potential DENV inhibitors.

Case Studies

Elucidation of Potential Inhibitors on DENV Protein Targets

DENV structural proteins

The envelope (E) protein

The E protein of DENV (DENV E) is responsible for receptor recognition, attachment of the virus on the host cell and endocytosis into the cell. It also participates in the fusion of the viral membrane with the host membrane (Harrison, 2008). This protein comprises three domains (Domains I, II and III) (Fig. 2) that have been pursued as drug targets. However, the hydrophobic pocket

Fig. 1 Targeted and targetable dengue proteins. (A) Structure of a dengue virus particle. (B) Steps in the infection process. Reproduced from Behnam, M.A.M., Nitsche, C., Boldescu, V., Klein, C.D., 2016. The medicinal chemistry of dengue virus. *J. Med. Chem.* 59, 5622–5649.

between Domains I and II (Modis *et al.*, 2003) is the most amenable and widely used for virtual screening or docking. Also known as the n-octyl- β -D-glucoside (β -OG) pocket, this domain acts as a hinge point between the two domains and plays a role in the conformational rearrangement necessary for the fusion process.

Wang and co-workers was among the first groups to utilize the β -OG as a target for virtual screens (Wang *et al.*, 2009). Noting the conformational flexibility of the pocket from the two crystal structures published by Harrison and co-workers (Modis *et al.*, 2003, 2004), they incorporated soft van der Waals contact parameters into the docking parameters as a

Fig. 2 Binding sites for identified DENV entry inhibitors on the crystal structure of DENV2 E protein dimer (PDB: 1OKE), shown in cartoon representation, coloured by secondary structure (helices in red and sheets in cyan).

compromise for the rigid protein requirement for docking. Compound (1) (**Fig. 3**) was the most potent compound as a result of this screen and verified by plaque reduction assay (EC_{50} = 0.068 to 0.496 μ M in the four DENV serotypes). Redocking of (1) into the β -OG pocket using GOLD software, revealed a similar pose to that of the amphiphilic β -OG, with its hydrophobic portion (chloro-phenyl-thiophene) buried within the space occupied by the octyl tail of β -OG. The polar pyridinyl-methyl-quinazolinyl-amine part of the molecule bound near the entrance of the pocket and was exposed to solvent but the phenyl group of the quinazoline ring had a hydrophobic interaction with Leu198 and possibly Pro53 or Ala205 while the amine hydrogen interacted with Glu49 or Thr48. In the same year, a multi-tiered docking screen of the Maybridge chemical database on the β -OG pocket resulted in the identification of five hit compounds which were then subjected to biological evaluation (Kampmann *et al.*, 2009). The most potent compound (2) (IC_{50} = 1.2 μ M), interestingly showed similar binding pose as that reported by Wang *et al.* suggesting a common pharmacophore for β -OG pocket binders across diverse chemical structures. Indeed, on hindsight, the discovery of two tetracycline derivatives as verified hits (IC_{50} = 55–67 μ M in a plaque reduction assay) against the β -OG pocket in an earlier *in silico* screen (Yang *et al.*, 2007) suggested that this binding site was particularly distinct. Of the ten hits initially identified, these tetracycline derivatives were found to dock at the entrance of the pocket and extended into the pocket, particularly between the D and I segments along the stretch of residues 48–52. In contrast, other inactive compounds were docked deeper inside the β -OG pocket.

A recent *in silico* screen against the β -OG pocket (Leal *et al.*, 2017) identified a quinazoline derivative (3) bearing some similarities to (1) as one of the hits. However, (3) showed a lower potency than (1) in a luciferase reporter assay of DENV (EC_{50} = 3.1 μ M). Despite adopting a novel “hybrid” design using motifs from two previous *in silico* screen hits (Li *et al.*, 2008; Zhou *et al.*, 2008), Jayaprakash and co-workers discovered (4) (EC_{50} = 1.39 μ M), the best hit which has several moieties of (2) (Jadav *et al.*, 2015). Results as these, where similarly structured hits were discovered, may be due to overlaps in the ligands available in the databases used in these virtual screening campaigns as much as the fact that the docking models were fundamentally based on the binding mode of β -OG.

Taking advantage of the shifting features of the DENV E domains during the fusion process, Yennamalli and co-workers attempted to search for alternative sites similar to the β -OG pocket on the E protein in both pre-fusion (PDB ID: 1OKE) and post-fusion (PDB: 1OK8) forms of the protein using a cavity-detection algorithm termed “putative active sites with spheres” (Yennamalli *et al.*, 2009). Two sites (named as Sites 1 and 2) were identified and were used in a large *in silico* docking screen of thirteen publicly and commercially available databases using a combination of GOLD, FlexX, and DOCK docking programs. After winnowing the hits against several criteria including drug-like features and chemical stability, seven compounds were biologically tested. The best compound (5), was able to reduce the plaque formation in infected Vero cells with an EC_{50} of 4 μ M thus validating these novel sites of DENV E for virtual screening of new and potential DENV entry inhibitors.

Fig. 3 DENV entry inhibitors identified from docking screens and verified experimentally.

The capsid (C) protein

The DENV Capsid (DENV C) is a 100 amino acid-length homodimeric protein with four α -helical regions and an intrinsically disordered NH terminal domain. A number of DENV C form a complex with the single-stranded viral RNA (nucleocapsid). They play a role in viral RNA recruitment during virus assembly and release of the genome during infection. Notably these RNA replication processes involve their interactions with the host intracellular lipid droplets and very low density lipoproteins (VLDL) (Byk and Gamarnik, 2016).

Research on the DENV C has just begun to shed light on its interaction mechanism with the host lipid entities (Martins *et al.*, 2012; Faustino *et al.*, 2015). Recent identification of key target ligands responsible for DENV C-lipid interactions such as apolipoprotein E and perilipin 3 (Faustino *et al.*, 2014; Carvalho *et al.*, 2012) has paved the way for the possibility of a structure-based discovery of DENV C binding inhibitors. However, there is presently no deposition of crystal structures of DENV C in the PDB except for a nuclear magnetic resonance (NMR) solution structure (PDB: 1R6R) (Ma *et al.*, 2004; Fig. 4). As such, very limited docking studies against this protein have been reported to date. The best lead for initiating such endeavours so far lies in the only small molecule DENV C ligand ST-148 which was fortuitously discovered in a high-throughput screening of a library of over 200,000 compounds (Byrd *et al.*, 2013). Docking analysis of ST-148 on the DENV C (PDB: 1R6R) suggested that the compound interacts with the protein thus enhanced its self-dimerization and this may have led to interference in the assembly and disassembly of the nucleocapsid necessary for RNA replication (Scaturro *et al.*, 2014).

DENV Non-Structural Proteins

NS1

NS1 is the first of seven non-structural proteins encoded for by the viral genome. It is a highly conserved 46 kDa non-structural glycoprotein of the DENV flavivirus, exists intracellularly, on cell surface and in secreted forms. NS1 plays an important role in viral particle production and viral RNA replication, presumably through post-translational N-glycosylation. NS1 contains two key N-glycosylation sites, located at Asn130 and Asn207, respectively, with Asn130 glycosylation site is more biologically important as Asn130 mutation has been shown to result in attenuation of dengue virus infection in both mammalian and mosquito cells (Tajima *et al.*, 2008).

To date, there is limited literature can be found with regards to *in silico* studies to discover novel NS1 inhibitors despite the fact that the crystal structure of DENV NS1 dimer has been solved (Fig. 5, PDB: 4O6B) (Akey *et al.*, 2014). The structure contains three domains: A small β -roll domain formed by two intertwined β -hairpins; a *Wing* domain, comprises an α/β subdomain and a discontinuous connector that sits against the β -roll and a β -ladder domain, formed by 18 antiparallel β -strands assembled in a continuous β -sheet that runs along the whole length of the dimer. Using this crystal structure, Qamar *et al.* (2014) attempted to identify potential inhibitors of Asn130 glycosylation site of NS1 by docking 2200 flavonoids from 405 medicinal plants using MOE docking program. Out of the top 100 flavonoids screened, six flavonoids showed significant interactions with Asn130, suggesting that flavonoids have potential to be DENV inhibitors, although further experimental evidence is required to support this observation.

Apart from the post-translational N-glycosylation, recent work found that NS1 also acts as an important modulator of cellular energy metabolism (Allonso *et al.*, 2015). Results from co-immunoprecipitation, cross-linking and ELISA assays have proposed that NS1 interacts with glyceraldehyde 3-phosphate dehydrogenase (GADPH), which results in the increase of glycolytic flux and ultimately the energy production, which is required for proper viral replication. *In silico* docking studies between the homology model of GADPH (PDB template: 1ZNQ) and the crystal structure of NS1 (PDB: 4O6B) using the web-based ClusPro server (Version 2.0; Kozakov *et al.*, 2017) revealed that the hydrophobic protrusion of NS1, located at the β -roll domain (Cys4, Val5, Leu13, Lys14, Cys15 of both monomers), interacts with the hydrophobic residues of GADPH located opposite its catalytic site. Interestingly, the NS1-GADPH binding interface is at a distant location from the N-glycosylation sites (Fig. 5), suggesting its potential as a novel target for the design and discovery of new drug candidate against the DENV viral replication.

NS2B–NS3 protease

NS3 is one of the most widely studied DENV proteins. It is a 69 kDa multifunctional protein which consists of 618 amino acids that carry two functional domains, the N-terminal trypsin-like serine protease domain and the C-terminus domain that contains the activities of a RNA helicase and a RNA-stimulated NTPase. The NS3 serine protease domain comprises 180 amino acid residues at its N-terminal with a catalytic triad formed by residues His51, Asp75 and Ser135 (Brinkworth *et al.*, 1999; Lescar *et al.*, 2008). The proteolytic activity of DENV NS3 protease (NS3pro) requires the NS2B protein, which is located in the polypeptide precursor

Fig. 5 (A) The crystal structure of DENV NS1 protein (PDB: 406B), in cartoon representation. (B) N-glycosylation sites (gold) and the GADPH binding site (cyan) of the DENV NS1 protein surface (blue). The separation between the N-glycosylation and GADPH binding sites suggest two possible targets for NS1 inhibitors as potential antiviral candidates.

upstream of the NS3pro domain, as a cofactor (Aleshin *et al.*, 2007). This structural activation probably resulted in conformational rearrangements of the catalytic triad and the subsite (S^5 - $S^{5'}$) residues, which facilitates substrate binding and/or optimizes proton exchange during catalysis (Barbato *et al.*, 1999; Kim *et al.*, 1996). NS2B-NS3pro is responsible for the cleavage of DENV C and for cleavage at the NS2A/NS2B, NS2B/NS3, NS3/NS4A, NS4A/NS4B and NS4B/NS5 boundaries (Chambers *et al.*, 1993; Arias *et al.*, 1993; Yotmanee *et al.*, 2015). Therefore, blocking or inhibiting the activities of DENV NS2B-NS3pro has become an attractive target in anti-dengue drug discovery.

To date, there are thirteen 3D structures of NS3pro from the four dengue serotypes deposited in the Protein Data Bank (PDB). In general, the crystal structures of NS3pro in complex with the cofactor NS2B for the four serotypes demonstrated that the NS3pro domain adopts chymotrypsin-like structure consisting two β -barrels of which each barrel contains six β -strands. The β -barrel conformation typically is compact with short or absent loop structures. The active site is located in between the cleft of the two β -barrels. It is relatively shallow, contourless and composed of a catalytic triad containing His51, Asp75 and Ser135 (Yildiz *et al.*, 2013; Noble *et al.*, 2012; Luo *et al.*, 2008, 2010; Erbel *et al.*, 2006; Chandramouli *et al.*, 2010).

The initial structure-activity relationship of NS2B-NS3pro can be inferred from well-established cleavage sites of DENV polyprotein by NS2B-NS3pro. The cleavage sites preferable by this enzyme usually occur after two basic amino acid residues (Lys-Arg, Arg-Arg or Arg-Lys) or occasionally after Gln-Arg at the P1 and P2 positions (Fig. 6) and are usually followed by a short side-chain amino acids, most commonly Gly, Ser or Ala at P1' (Chambers *et al.*, 1990). A functional substrate profiling of the P1-P5 and P1'-P5' regions of the proteases from the four DENV serotypes showed that the enzyme shared very similar substrate specificities across the serotypes (Khumthong *et al.*, 2002; Chanprapaph *et al.*, 2005) with recent finding shows that the interaction between these substrates with the NS2B/NS3 protease is in the order of DENV C > intNS3 > NS2A/NS2B > NS4B/NS5 > NS3/NS4A > NS2B/NS3 (Yotmanee *et al.*, 2015) which is in agreement with experimental values.

Two tetrapeptides, Bz-Nle-Lys-Arg-Arg and Bz-Nle-Lys-Thr-Arg have been shown to have high affinities for NS2B-NS3pro (K_i =12.42 and 33.9 μ M, respectively) (Yin *et al.*, 2006). A stepwise removal of the octapeptide down to tetrapeptide i.e., WYCW-NH₂ resulted in protease inhibition in low micromolar activities (K_i =4.2, 4.8, 24.4 and 11.2 μ M for DENV1-4, respectively) (Prusis *et al.*, 2013). The docked pose of the tetrapeptide on DENV3 is shown in Fig. 7. Tripeptide with a varied N-terminal cap groups and P2 Lys' side chain modification have also been shown to have micromolar activities against DENV2 NS2B-NS3pro. It was suggested that P2Arg play the specificity shift towards the protease while an extended P2 Lys failed to block the protease activity, suggesting a size-constrained S2 pocket (Schüller *et al.*, 2011).

Over the past ten years, there have been many efforts to search for small molecules anti-dengue through the mean of *in silico* approaches that target NS2B/NS3-protease. Many compounds either small molecules from natural products or synthetic chemicals have been discovered as potential inhibitors for the enzyme. Two cyclohexyl chalcone derivatives, 4-hydroxypanduratin A (Fig. 8: 6) and panduratin A (Fig. 8: 7) isolated from *Boesenbergia rotunda* (L.) Mansf. Kulturpfl. have shown good competitive inhibitory activity with K_i values of 21, and 25 μ M, respectively (Tan *et al.*, 2006). The discovery has prompted the docking studies

of these compounds which led to the synthesis of ethyl 3-(4-(hydroxymethyl)-2-methoxy-5-nitrophenoxy)propanoate (Fig. 8: 8) which also have strong inhibition ($K_i=59\ \mu\text{M}$) (Kee *et al.*, 2007). Docking noncompetitive inhibitors (Fig. 8: 9–14), which were previously isolated (Tan *et al.*, 2006) using AutoDock3 (Morris *et al.*, 1998) showed that these noncompetitive ligands bound to the allosteric sites, particularly at the backbone carbonyl of Lys74 (which is bonded to Asp75, one of the catalytic triad residues) of DENV2 NS2B-NS3pro, the results of which, are in accordance with the experimental study (Chandramouli *et al.*, 2010). Based on these results, three series of panduratin A derivatives (i.e., of 246DA (15), 2446DA (16) and 20H46DA (17)) were designed by adding various substituents at the positions 1–5 of the benzyl ring A for both 4-hydroxypanduratin A and panduratin A. A docking calculation of these substituted benzyl compounds with NS2B/NS3pro showed favourable binding energies which are close to the computed energy of the parent compounds (Frimayanti *et al.*, 2011).

Noncompetitive inhibition of NS2B-NS3pro especially that involved binding at the allosteric sites continues to generate interests in many researches. Previously, the 3F10 antibody was found to disrupt the interaction of NS2B with NS3 *in vitro*, which suggest the possibility of NS2B-NS3pro allosteric inhibition (Phong *et al.*, 2011). Docking analysis of the noncompetitive inhibitors screened from 13,341 small compounds, with the backbone structures of chalcone, flavanone, and flavone, available in the ZINC database, showed four compounds (Fig. 9: 18–21) (the most potent, compound (Fig. 9: 18) with $K_i=69.9\ \mu\text{M}$) formed hydrogen bonding interactions with the amino acid residues Glu88, Gly124, and Asn167, as well as π -cation interactions with Lys74. This site is located behind the active site (Ser135, Asp175, and His51) (Heh *et al.*, 2013). Allosteric region near Ala125 has also been proposed as a target for the binding of noncompetitive NS2B-NS3pro inhibitors. Ala125 sits between the 120s and 150s loops, which have been shown to be very flexible (Yildiz *et al.*, 2013). Other allosteric sites including that formed by the amino

Design and evaluation of substrate-based octapeptide and non substrate-based tetrapeptide inhibitors of dengue virus NS2B-NS3 proteases. *Biochem. Biophys. Res. Commun.* 434, 767–772.

acids Trp89, Thr120, Gly121, Glu122, Ile123, Gly124, Gly164, Ile165, Ala166, and Gln167 of NS3 and Lys73, Lys74, Asn152, Val78, Gly82, and Met84 of NS2B has been identified and used in the design of eight potent NS2B-NS3pro inhibitors (22–29) (IC_{50} = 1–98 μ M, **Table 1**) (Wu *et al.*, 2015).

Virtual screening of large chemical databases such as Maybridge, ChemBridge and ZINC databases have aided the discovery of many potent compounds as well as scaffolds for further optimisation. 300,000 compounds were docked using AutoDock 3 (Morris *et al.*, 1998) on the GVSS platform and led to the identification of seven novel inhibitors (IC_{50} ~ 4.0–90 μ M) with three of them as competitive inhibitors (K_i ~ 3.0–5.0 μ M). The inhibitors were stabilised by forming H-bonds with the catalytic residues (His51 and Asp75) and through hydrophobic interactions with various amino acids in the NS3pro active site pocket (Nguyet *et al.*, 2013). In another virtual screening campaign, compound (30) was found to be active against NS2B-NS3pro (IC_{50} = 13.12 ± 1.03 μ M) and was used to design fourteen derivatives which in turn lead to the discovery of four new inhibitors with biological activity. Based on the results, small molecule-based scaffold hopping was performed to design new compounds which led to the discovery of 17 novel NS2B-NS3pro inhibitors with IC_{50} values of 7.46 ± 1.15 to 48.59 ± 3.46 μ M (Deng *et al.*, 2012).

Fragment-based virtual screening approach has also been applied to discover small molecule inhibitors of DENV NS2B-NS3pro (Knehans *et al.*, 2011). Since suitable co-crystal structure of DENV-2 protease with bound inhibitor was unavailable at that time, the homology model of DENV-2 NS2B-NS3pro (derived from various flavivirus NS2B-NS3pro structures) was used to screen 150,000 molecular fragments collected from ZINC database using AutoDock Vina (Knehans *et al.*, 2011; Trott and Olson, 2010) focusing on the interactions with the S1 and S2 pockets of NS2B-NS3pro. High scored fragments were then linked to generate new bioactive molecule where docking analysis showed that this compound interacted with S1 pocket (Asp129) *via* hydrogen bonding and electrostatic interaction. 23 compounds were tested experimentally that led to the identification of two inhibitors, compounds (31) and (32) (IC_{50} = 7.7 μ M and 37.9 μ M, respectively).

There are many other docking studies as well as virtual screenings using docking which have been performed and able to give insight into the binding of potential NS2B-NS3pro. However, they are not validated experimentally, making it difficult to assess the successful of their *in silico* prediction. Such examples include Qamar *et al.* (2014) who had carried out a docking analysis with DENV NS2B-NS3 protease using a library of 940 phytochemicals. In their study, they found *Garcinia* phytochemicals to be their best hits, including gossypol, mangostenone C, garcidepsidone A, and dimethyl- calabaxanthone bound deeply inside the active site of DENV NS2B/NS3 protease among all tested phytochemicals and had interactions with catalytic triad (His51, Asp75, Ser135). In another study, a molecular docking analysis (using Molegro Molecular Docker (Thomsen and Christensen, 2006)) of 2194 plant-derived secondary metabolites with dengue virus protein targets carried out by Powers and Setzer (2016), showed that 24 compounds docked strongly to dengue virus NS2B-NS3 protease ($E_{\text{dock}} < -130$ kJ/mol) (Powers and Setzer, 2016). The lowest-energy docking poses of the chalcone ligands balsacone A, balsacone B, and balsacone C, bound into both the binding site of Lys-Arg as well as the catalytic site occupied by the co-crystallized inhibitor M9P. Although all these findings have not been validated experimentally, they did provide some insights into the development of DENV NS2B-NS3pro inhibitors.

NS3 helicase

Besides having the protease activity, the C-terminal fragment of NS3 behaves as an ATP-dependent RNA helicase and unwinds the double-stranded RNA genome during virus replication (Utama *et al.*, 2000). The helicase activity (Gorbalenya *et al.*, 1989; Li *et al.*, 1999) is vital in virus replication as it separates dsRNA during viral replication. The crystal structure of DENV-2 helicase catalytic domain revealed a three-lobed flattened topology with a large number of loops. It has a distinct structural feature with a long tunnel runs across the centre of one face of the protein (Xu *et al.*, 2005; Behnam *et al.*, 2016; Swarbrick *et al.*, 2017).

Fig. 8 Structures of the competitive (4-hydroxypanduratin A (**6**), panduratin A (**7**)) and noncompetitive inhibitors (**9–14**) isolated from *Boesenbergia rotunda* (L.) Mansf. Kulturpfl. (Ethyl 3-(4-(hydroxymethyl)-2-methoxy-5-nitrophenoxy) propanoate (**8**), and panduratin A derivatives (**15–17**) are synthetic competitive inhibitors).

Therefore, due to its role in virus replication, NS3 helicase has also been considered as a target with high potential to develop dengue antiviral agents. There is limited information available on molecular docking involving this target. Recently, Halim and co-worker highlighted both structure and ligand-based approach in search of potential NS3 inhibitor from ZINC database (Halim *et al.*, 2017). A pharmacophore model generated using 16 compounds from literatures (Basavannacharya and Vasudevan, 2014; Sweeney *et al.*, 2015; Mastrangelo *et al.*, 2012) was used to filter 1,201,474 compounds from the ZINC database. Molecular docking using FRED docking program was then conducted on those compounds which fit the pharmacophore model. 25

compounds with drug-like properties were selected and postulated as potent inhibitors for NS3 helicase. This postulation however, is not validated experimentally.

Since the crystal structure of this enzyme is only recently available, Milani and co-worker had initiated an investigation of DENV NS3 helicase using a built 3D model based on other flavivirus (Milani *et al.*, 2009). *In silico* screening was conducted against virtual Library of Pharmacologically Active Compounds (LOPAC) which included 1280 commercially available compounds from

Sigma Aldrich (see “Relevant Website section”) using Autodock 4. Three best compounds were selected namely paromomycin sulphate, ouabain and ivermectin displaying ΔG values between −11.5 and −9.5 kcal/mol. These compounds were found to interact with Arg409 and Tyr410. These compounds were then further tested experimentally using numerous *in vitro* approach from enzymatic to cell-based assay to rule out all non-specific inhibition of NS3 helicase. They proved that ivermectin behaves like uncompetitive helicase inhibitor which only binds to protein/RNA and blocks the enzymatic activity. However, the results from cell-based assay is not able to exclude the possibility that ivermectin exerts its antiviral activity on DENV *via* other mechanism (Mastrangelo *et al.*, 2012).

NS4

NS4A and NS4B are integral membrane proteins which play multiple roles in viral replication and virus-host interaction (Zou *et al.*, 2015). To date, only one *in silico*-based drug discovery campaign on NS4B was performed. Although Paul and co-workers proposed that three of the seven docked bioactive phytochemical compounds on the NS4B protein models of DENV1-4, i.e., (-)-catechin, epicatechin and DL-catechin, have the potential to be developed into effective anti-dengue drugs on DENV-1,2 and 4, however, it is unclear how the authors came to this conclusion as the predicted binding energies of these compounds were modest (< −6 kcal/mol) and they were not validated experimentally (Paul *et al.*, 2016).

NS5

NS5 is the largest and most conserved protein in the dengue genome. It contains two functional domains, i.e., the RNA methyltransferase (MTase) domain at its N-terminus and the RNA-dependent RNA-polymerase (RdRp) domain at its C-terminus. MTase is highly important for mRNA stability, protein synthesis and viral replication as it is involved in the last two steps of mRNA capping process, i.e., transferring a methyl group from S-adenosyl-L-methionine (SAM) onto the N7 position of guanine-N7 methyltransferase (cap guanine) and to the 2′O position of the first nucleotide following the cap guanine (nucleoside-2′-methyltransferase), generating S-adenosyl-L-homocysteine (SAH) as the by-product. On the other hand, RdRp domain is involved in the generation of both minus and plus RNA strands, thus its role in viral RNA replication. Recently, Ahmad Jamil and co-workers have proposed based on their protein-protein docking results with HADDOCK that NS5 may also interact with the host protein SIAH2 which would then binds to STAT2 protein and results in the ubiquitination of the host proteins involved in IFN-mediated antiviral effect (Aslam *et al.*, 2015). This, however, remains to be confirmed by wet-lab experiments.

Fig. 10 Chemical structures of the inhibitors of NS5 (MTase domain) with their corresponding IC_{50} values from *in vitro* bioassays.

In the past decade, various research groups have attempted to find inhibitors of MTase, targeting either the S-adenosylmethionine (AdoMet/SAM) or the RNA cap site (GTP site), using a combination of computational and experimental techniques. [Luzhkov *et al.* \(2007\)](#) performed a high-throughput based virtual screening from 2.1 million commercially available compounds using 2D similarity searching, pharmacophore filtering based on the structure of SAH, and docked onto the SAM site of the NS5MTaseDV (dengue virus mRNA cap (nucleoside-2'O)-methyltransferase) with GOLD docking software ([Luzhkov *et al.*, 2007](#)). The 15 top-ranked compounds were then tested with bioassay test on recombinant MTase in competition with the RNA substrate. A novel inhibitor scaffold, (**33**) with IC_{50} value of $60 \mu M$ was identified from this approach ([Fig. 10](#)). Interestingly, investigation into the docked complex between (**33**) and the SAM site of MTase revealed that (**33**) did not form important polar interactions with Asp79, Trp87, Gly106, Glu111 and Asp131 at the binding site as SAH. Rather, the efficient binding of (**33**) is due to its good complementary fit to the target site. Similarly, [Milani *et al.*](#) successfully identified a non-specific inhibitor, ATA, (**34**) with $IC_{50} = 2.3 \mu M$ (RNA cap site); $127 \mu M$ (SAM site) from *in vitro* assay of the top three ranked *in silico* docked compounds from 1280 commercially available compounds in the LOPAC library with AutoDock4. Another successful example is by [Podvinec *et al.* \(2009\)](#) who performed a multistage docking of more than 5 million commercially available compounds against the two binding sites of MTase with Glide, followed by experimental verification of 263 best compounds with MTase enzyme inhibition assay ([Podvinec *et al.*, 2010](#)). Four inhibitors with IC_{50} of $< 10 \mu M$ in *in vitro* assay were successfully identified from this work, although only 2 of the four compounds were found later to be genuine, non-aggregating, low micromolar inhibitors (compounds (**35**) and (**36**), [Fig. 10](#)).

Recently, [Benmansour *et al.* \(2016\)](#) attempted to use *in silico* docking to guide fragment linking of 3 of the 7 fragment hits bound close to SAM binding site (IC_{50} values range between $180 \mu M - 9 mM$) identified from a 500 fragments library *via* thermal shift assay, fragment-based x-ray crystallography screening, and enzymatic assays ([Benmansour *et al.*, 2017](#)). Analogues with different linkers at different positions of the two fragment hits were designed using the Link Multiple Fragment Tools of MOE and docked with and without 3D-pharmacophore constraint using MOE Docking tool and Glide, respectively. As only amide and urea-

Fig. 11 Binding sites on RdRp domain of NS5 (PDB: 2J7U). Reproduced from Yap, T. L., Xu, T., Chen, Y. L., *et al.*, 2007. Crystal structure of the dengue virus RNA-dependent RNA polymerase catalytic domain at 1.85-angstrom resolution. *J. Virol.* 81, 4753–4765. Surface as potential drug targets with the active/catalytic site (red) and allosteric site (cavity B, magenta; pocket II, cyan). Chemical structures of the inhibitors at each site are shown with their corresponding IC_{50} values from *in vitro* bioassays.

based linker were able to maintain the correct orientation of the initial fragments, various analogues with these linkers were synthesized and tested. Ultimately, this led to a novel series of non-nucleoside inhibitors (N-phenyl-[(phenylcarbamoyl) amino] benzene-1-sulfonamide and phenyl [(phenylcarbamoyl) amino]benzene-1-sulfonate derivatives) with a 10–100-fold stronger inhibition of 2'-OMTase activity compared to the initial fragments (IC_{50} =91–452 μ M). Their activities in the virus inhibition assay, however, remain uninspiring, presumably due to intrinsic low activity *ex vivo* or their poor ability to cross membrane. Other potential inhibitors of MTase that have been reported include cyclic peptides CTWYC and [Tyr123] human Prepro Endothelin (110 – 130) (SAM site), cyclic peptides CYEFC and human urotensin II (RNA-cap site) (Tambunan *et al.*, 2014; Idrus *et al.*, 2012), phytochemical compounds (isoborreverine, diplacone, styracifolin B, neosilyhermin A, and β -[4-hydroxy-5-(5-hydroxytigloyloxy)tigloyl]-santamarin), SAH analogues (e.g., SAH-M331, SAH-M2696, SAH-M1356) (Tambunan *et al.*, 2017; Singh *et al.*, 2016) and ribavirin analogues (Sivakumar and Sivaraman, 2011). These ligands, however, were identified solely by *in silico* docking and molecular dynamics simulations, and thus further validation by *in vitro* assays is warranted.

While MTase domain remains the mainstream target for the inhibition of NS5 protein for the past decade, RdRp domain is becoming more popular in recent years. According to Yap *et al.* (2007), RdRp domain can be divided into three key subdomains, i.e., fingers, thumb and palm domains, stabilised by the NLS region, with loops L1, L2 and L3, linker α 21- α 22 and the priming loop encircling the catalytic active site (GTP site) and shaping the template tunnel (Fig. 11).

To date, most inhibitors of the RdRp domain of NS5 focus on either the active catalytic site or the allosteric sites in the thumbs domain. To illustrate, a highly specific, pyridoxine-derived small molecule inhibitor, (37) (DMB220) (IC_{50} =5–6.7 μ M in enzymatic assay, EC_{50} < 3 μ M in antiviral cell-based assay) was designed as an active-site metal ion chelator to chelate divalent metal ions in the catalytic site of DENV RdRp. Docking studies with AutoDock Vina suggest that it interacts with active site residue Asp533, Asp663 and Asp664, with its sulfoxide oxygen and hydroxyl groups on the pyrimidine ring coordinates with both Mg ions at the active site (Xu *et al.*, 2015). Similarly, Cheng *et al.* (2016) reported a new and potent, highly selective antiviral compound, (38) (zoanthone A, EC_{50} =19.6 μ M, CC_{50}/EC_{50} =36.7), isolated from ethanolic extract of plant *Zoanthus spp* (Cheng *et al.*, 2016). (38) formed three hydrogen bonds between C-6=O and charged NH residue of Arg729, OH-2 and backbone NH of Trp795, as well as OH-20 and NH at imidazole side chain of His798 of the NS5 RdRp tunnel, suggesting that the carbonyl group at C-6 and hydroxyl group at C-2 in ecdysone skeleton is essential for their bioactivities, in agreement with the SAR results of the ecdysone analogues performed. On the other hand, Milani and co-workers found that the top two (out of the 203) docked compounds on the protein active site of DENV-3 RdRp (Tarantino *et al.*, 2016) (PDB 2J7U) (Yap *et al.*, 2007) with AutoDock 4.2, the pyridobenzothiazole compound, HeE1-2Tyr, (39), was found to be able to inhibit Dengue RdRps' activity (IC_{50} DENV3 RdRp= 1.5 μ M) and showed antiviral activity in cell culture against all four DENV serotypes (IC_{50} 6.8–15 μ M). Other potential inhibitors of RdRp domain targeting the active site include plant-derived secondary metabolites (i.e., dimethylisoborreverine, drummondin

D, flinderole B, and pungioid A), quercetin derivatives (i.e., quercetin 3-(6''-(E)-p-coumaroylsophoroside)-7-rhamnoside) and fragment-derived inhibitor (i.e., [2-(4-carbamoylpiperidin-1-yl)-2-oxoethyl]8-(1,3-benzothiazol-2-yl)naphthalene-1-carboxylate) (Yap *et al.*, 2007; Powers and Setzer, 2016; Anusuya *et al.*, 2016; Anusuya and Gromiha, 2016).

Apart from targeting the active site, various groups have also come up with inhibitors targeting the allosteric sites of NS5 RdRp. For example, Vincetti *et al.* (2015) performed virtual screening on the cavity B of DENV-2 NS5 RdRp (Leu328, Lys330, Trp859, Ile863) from a library of about 3000 known tyrosine protein kinase, Src active scaffolds (ChEMBL, BindingDB databases) and 10,000 virtual synthetically accessible compounds designed in house using the SmiLib v2.0 with both Glide and AutoDock Vina and found that purine derivatives were able to inhibit DEN-2 replication in virus cell-based assay (EC₅₀: 5–20 μ M) while (40) also inhibit NS3-NS5 interaction (33% inhibition at 50 μ M concentration), presumably due to the hydrophobic contacts and cation- π interactions between purine and the side chain of Lys330. Similar observation was made by Venkatesham *et al.* (2017) for their purine lead compound, (41) and quinazoline lead compound, (42) with EC₅₀ of 1.9 μ M and 2.6 μ M, respectively, although the reported binding modes varied slightly from Vincetti's, presumably due to difference in type of docking programme used. In a separate study, the most potent 4-thiazolidinone analogue, (43) was found to bind to pocket-II of the thumb domain *via* hydrophobic interactions with Ala776, Met809, Cys780, Ser785, Trp833, Thr880 and Tyr882, hydrogen bond interaction with backbone of Pro884, and electrostatic interaction with amide side chain of Asn777 of DENV-2 NS5 model, as predicted by molecular docking and confirmed by the fluorescence quenching assay (Manvar *et al.*, 2016). On the other hand, 39 non-nucleotide compounds, consisting of natural compounds and NITD1/2/29 analogues, were predicted *in silico* to bind strongly to a binding site at the RNA template tunnel (e.g., Arg737, Thr413, Met343 in DENV-3) (Galiano *et al.*, 2016).

Discussion and Future Direction

Progress in structural biology has successfully elucidated the structures of various proteins of dengue which certainly has contributed to vast efforts in computer-aided drug discovery of many potential anti-viral dengue inhibitors in the last ten years. Many studies have focused on the DENV E protein due to the fact that multiple of this protein cover most of the surface area of the viral particle. Furthermore, the knowledge of its conformational changes as well as well-defined crystal structures in the fusion event have created several binding site targets for potential DENV entry inhibitors such as β -OG pocket (the hydrophobic pocket), stem region and the domain III (Modis *et al.*, 2003, 2004).

DENV E protein has a key role in viral entry to the cells. It provides attachment through receptor interaction and subsequent endosomal fusion. Inhibiting the entry of the dengue virus to the cell thereby avoiding the infection is an attractive way to develop potent and specific dengue antivirals. These molecules would exert their effects without having to enter the cells, thus not subjected to strict structural and chemical constraints and may potentially limits the immune system hyperactivation that could lead to severe dengue (De La Guardia and Leonart, 2014).

Perhaps a different approach to target the DENV E is through preventing it from establishing contacts with other proteins of the virus or the host cell for viral adsorption (Perera-Lecoin *et al.*, 2013). The discovery of some large molecular weight polysaccharides such as curdlan sulphate (Ichiyama *et al.*, 2013) and 3-O-sulfated GlcA (Hidari *et al.*, 2012) that were able to inhibit virus entry pointed to this possibility. Docking simulations with the active compounds predicted their binding to sites in which DENV E interacts with the host receptor such as the glycosaminoglycan receptors. A similar approach using a peptide that mimics the ectodomain of the DENV M protein (Panya *et al.*, 2014) also suggested the ability of the peptide inhibitor MLH40 to disrupt protein-protein interaction as predicted by their docking experiment. To date, no small molecules (m.w. < 500), were reported as hit compounds targeting these protein-protein "contact" sites of the E protein and thus, there is an immense opportunity to venture on finding small molecules targeting these receptor binding sites on DENV E.

Most of the entry inhibitors are peptidic compounds. Similarly, this class of compounds has also been considered as DENV protease inhibitors. Although the peptidic or peptidomimetic compounds are able prevent fusion to take place or inhibit DENV protease in low micromolar concentration, they do not possess drug-like structure. Thus, they will be likely to encounter physicochemical stability as well as pharmacokinetic problems during further stage of drug development. It is thus not surprising that, currently, no peptide inhibitor has been clinically used as a dengue antiviral agent. However, the knowledge of how these peptide inhibitors bind to DENV drug targets can be applied to derive a model with certain pharmacophoric features which in turn can be used in designing small molecule inhibitors (Gao *et al.*, 2010; Steuer *et al.*, 2011).

Other proteins such as C, NS2B-NS3 protease, NS3helicase, NS4 and NS5 are also feasible targets to look into in the screening for antiviral inhibitors. However, lack of crystal structure has hampered the discovery of potential binders to the capsid (C). High resolution crystal structures with well-defined binding sites are very much preferable in conducting molecular docking studies, the fact of which is true to the case of DENV NS2B-NS3 protease which has no doubt been the most favourite target for discovery of DENV antiviral agent as reviewed above.

NS2B-NS3pro is a chymotrypsin-like protease that has a catalytic triad formed by His51-Asp75-Ser135, which is essential for its substrate cleavage activity. In addition to the catalytic triad, Gly151 and Gly153 are also important residues as they participate in the formation of the oxyanion hole (along with Ser135) to stabilize the tetrahedral intermediate. This active site of the protease is flat and it would require a substantial conformational change in NS2B to enable the inhibitor to bind, thus, represent a major obstacle for the inhibitor to bind (Aguilera-Pesantes *et al.*, 2017). However, this limitation has not stalled the progress in searching for potential inhibitors as many researchers have also considered the inhibitors that target allosteric binding sites. In fact, a review

by Leonel *et al.* (2018) showed that about 3,384,268 molecules including nitro, catechol, halogenated and quarternary compounds have been evaluated for the NS2B-NS3pro inhibition activity. However, none of them has entered clinical studies presumably that their toxicity, pharmacokinetic and pharmacodynamic (*absorption, distribution, metabolism, and excretion* and toxicity: ADMET) properties have yet to be characterised.

Most of the earlier researchers attempted to discover peptidic inhibitors targeting the active site, based on their understanding of cleavage activities of DENV polyprotein by NS2B-NS3pro. The cleavage sites preferable by this enzyme usually occur after two basic amino acid residues (Lys-Arg, Arg-Arg or Arg-Lys) or occasionally after Gln-Arg at the P1 and P2 positions. However, the host serine protease such as furin also recognises the two basic amino acid residues at P1 and P2 positions, thus, the selectivity and toxicity of the potential inhibitors might represent significant issues during the development stage. This limitation thus must be taken into account during the development of DENV NS2-NS3pro inhibitors. Considering other targets for DENV virus, which do not have any resemblance with the host proteins such as that displayed by DENV NS5 RNA-dependent RNA polymerase (RdRp) would be a good alternative as inferred from previous knowledge of antiviral agents that are now in clinical trials. This enzyme plays a critical role in viral replication by forming part of a multimeric complex. As there is no equivalent to flavivirus RdRp in the human host cells, DENV NS5 inhibitors are most likely to have little or no toxicity issues.

However, this fact is not true to the DENV NS5 inhibitors under current development. Although a lot of researches are ongoing in the search for inhibitors of NS5, in particular the RdRp protein, none of these potential drug leads has actually reaches clinical trial. To illustrate, the nucleoside analogue, NITD008, which showed significant reduction in DENV 1–4 replication in *in vitro* studies, appeared to be highly toxic in mice (Yin *et al.*, 2009). Similarly, various non-nucleoside inhibitors were also found to be either toxic in animal model or having poor inhibition potency (El Sahili and Lescar, 2017). The present drug for Hepatitis C virus (HCV), e.g., balapiravir, which are supposed to bind to RdRp protein of dengue (as both dengue and HCV shares similar architecture of RdRp), is found to be ineffective against the dengue RdRp protein (Nguyen *et al.*, 2013). These suggest that the search of novel inhibitors of RdRp that are potent and less toxic is highly essential. As this protein is highly druggable, with many potential druggable sites, including the active site and various allosteric sites, and with multiple crystal structures available, RdRp NS5 still definitely is an attractive target for *in silico*-guided design and discovery of novel dengue antiviral agents.

The review has highlighted many case studies which yield many potent compounds that could be developed further as dengue antiviral agents. However, it is worth noted that docking alone might not be sufficient to create molecules with high potential as dengue antiviral agent. One should elucidate further the pharmacophoric features of the active compounds or thorough mechanism of action by molecular dynamics simulation or a hybrid quantum/molecular mechanics (QM/MM) method before proceeding to lead optimisation. Multi-step *in silico* approach is valuable for optimisation of hit compounds discovered by virtual screening or molecular docking. Pharmacophore modelling, 3D quantitative structure-activity relationship (QSAR), fragment and scaffold hopping could be used further to optimise the hits reported in the literature for inhibitors with better activity. As demonstrated by Deng *et al.* (2012), small molecule-based scaffold hopping was able to optimise compound 30 (Fig. 9) identified from virtual screening using docking (verified active against NS2B-NS3pro with $IC_{50} = 13.12 \pm 1.03 \mu M$) towards to the discovery of 17 novel NS2B-NS3pro inhibitors with IC_{50} values of 7.46 ± 1.15 to $48.59 \pm 3.46 \mu M$. In addition, the other future direction that should be considered is the evaluation of ADMET of these already discovered potential inhibitors. *In silico* approaches for ADMET have reached maturity and can be utilised, albeit, must be eventually validated by *in vitro* or *in vivo* experiments.

Taking novel compounds either new peptidic or small molecules from research to clinic is a daunting task and take a long time and resources. Drug repurposing has been considered by many researchers as it can significantly reduce the cost and development time as these off-patent, already marketed drugs, have demonstrated *safety* in humans and thus negates the need for Phase I clinical trials (Oprea *et al.*, 2011). Many researchers have conducted virtual screening as the starting point for drug repurposing for dengue inhibitors. Using *in silico* docking to explore the single-strand RNA access site within WNV helicase, ivermectin, a broad spectrum antiparasitic drug, was identified as potential inhibitor of NS3 helicase (Milani *et al.*, 2009). Ivermectin displayed uncompetitive inhibition of flaviviral helicase unwinding activity in biochemical assays in the upper nanomolar range for WNV and DENV but did not affect the ATPase activity of the NS₃ helicase domain. In cell culture, ivermectin caused virus titer reduction with an EC_{50} of $0.7 \mu M$ for DENV and $4 \mu M$ for WNV (Mastrangelo *et al.*, 2012). Clinical trial involving ivermectin sponsored by Mahidol University and The Thailand government (clinical trial identifier: NCT02045069) is underway although the results on the clinical safety and efficacy have yet to be published as far as we are aware. Ivermectin is a natural product isolated from bacteria. The structure is rather big (m.w. = 875.10 g/mol), therefore might pose problem during absorption. Structure optimisation using either structure-based or ligand-based design could be further carried out to yield analogues with more desirable properties. Moreover, ivermectin is commercially used as a topical preparation for parasite, and thus its administration by oral route deserves to be studied more carefully. Ivermectin is just one example of potential drug for anti-dengue discovered *via* drug repurposing. Perhaps, more rigorous *in silico* drug repurposing would be able to discover other already marketed or off-patent drugs as clinical dengue antiviral agents.

Concluding Remark

Over the last decade, significant number of researches had been reported using computational docking approach in dengue drug discovery. As discussed earlier, either at the preliminary stage *via* high-throughput screening to confine the search from huge number of compound databases or to further predict the potential interaction from the selected hit, molecular docking no doubt

aids in identifying potential hits. Nevertheless, it is also important to note that the integration of other computational approaches such dynamics study, QM/MM and QSAR will serve to enhance the chances of the elucidation of credible potential hits.

Drug Repurposing: Polypharmacology, Benefits and Drawbacks

Drug repurposing is based on polypharmacology, a field of study related to design, discovery, synthesis, and use of pharmaceutical agents (drugs, small molecules, antibodies, stabilized peptides, natural products, etc.) that act on multiple targets (genes or gene products) or disease pathways. Complex diseases (such as neurodegenerative diseases and cancers) involve networks of multiple genes, hence necessitate multi-pharmacophores as a part of their therapeutic and system biology-based approaches. By specifically regulating multiple targets, more effective drugs can be developed through polypharmacology (Anighoro *et al.*, 2014). In need of treatment for critical illnesses and neglected diseases, efforts to match old drugs, that are already known to be safe and/or approved by US Food and Drug Administration (FDA) for diseases are in ongoing demand.

Since pharmaceutical agents can interact with multiple targets, unintended interactions between drugs and off-targets could result in toxicities or side effects. Side effects arising from a particular drug have been serendipitously used to usher a new use, such as treating other conditions and diseases. For example, sildenafil, commercially known as Viagra, is a blockbuster drug used to treat male erectile dysfunction; Viagra's clinical effects on treating erectile dysfunction were observed when it was studied for treating hypertension (Reaume, 2011).

Drug repurposing can reduce healthcare costs, given how laborious, time-consuming, and costly *de novo* drug discovery projects have been. Drug-candidate molecules that have been shown as being safe, yet insufficiently effective for the intended target (Oprea *et al.*, 2011), can be considered for other targets, hence possibly reducing the costs of clinical trial. The increasing amount and availability of public and open source databases, knowledge, algorithms, and servers, have encouraged more participants of drug repurposing projects.

Drug discovery efforts have resulted in discovery of new modes of actions for approved drugs. For example, Fasudil is a Rho-kinase inhibitor and vasodilator, which was repurposed to improve memory and treat several neurodegenerative disorders (Iorio *et al.*, 2010), such as Alzheimer's disease. In addition, orphan, rare, and neglected diseases with limited fundings have benefited from drug discovery efforts. For example, closantel, a veterinary anthelmintic, was repurposed to inhibit the chitin metabolism of the filarial nematode *Onchocerca volvulus*, that causes a neglected tropical disease Onchocerciasis (river blindness) (Gloeckner *et al.*, 2010). Drug repurposing has also been achieved through combining approved drugs (multidrug cocktails) in novel ways to synergistically treat diseases, including HIV infection, cancer, and *Mycobacterium tuberculosis* infection (Borisy *et al.*, 2003).

While drug repurposing brings numerous benefits, there are associated drawbacks of such an effort. Our understandings of the pathways and mechanisms of many complex diseases remain incomplete (Reddy and Zhang, 2013), yet efforts for drug repurposing often require analyzing complete data. Public databases have increasingly provided enormous information that can facilitate drug repurposing, yet they are non-synchronized (Wiegiers *et al.*, 2009). According to Oprea *et al.* (2011), there is no systematic mechanism to obtain fundings to support drug repurposing projects hitherto, in comparison to *de novo* drug discovery projects. To address this challenge, drug discovery project leaders have sought limited fundings from private and/or non-for-profit organizations, such as the Bill & Melinda Gates Foundation, Howard Hughes Medical Institute, and Simons Foundation.

Databases and Computational Resources for Drug Repurposing

The process of a new drug development is costly and time-consuming, and therefore drug repurposing has emerged as a time-efficient and cost-effective strategy to discover new indications for already approved drugs (Fu *et al.*, 2013). A number of available and searchable drug databases has been designed and developed for supporting drug repurposing studies such as PROMISCUOUS (von Eichborn *et al.*, 2011), DRAR-CPI (Luo *et al.*, 2011), e-Drug3D (Pihan *et al.*, 2012), PharmDB (Lee *et al.*, 2012), PharmDB-K (Lee *et al.*, 2015), DrugPredict (Simon *et al.*, 2012), DrugMap Central (Fu *et al.*, 2013), DrugBank (Law *et al.*, 2014), RE:fine drugs (Moosavinasab *et al.*, 2016), Mantra 2.0 (Carrella *et al.*, 2014), repoDB (Brown and Patel, 2017), RepurposeDB (Shameer *et al.*, 2017), SIDER (Kuhn *et al.*, 2016), SWEETLEAD (Novick *et al.*, 2013), DeSigN (Lee *et al.*, 2017), and Connectivity Map (Cmap) (Lamb, 2006).

PROMISCUOUS database (see "Relevant Websites section") contains comprehensive data of drug-target interaction, drug side effect, and protein-protein interaction data. PROMISCUOUS has been proven to be useful for drug repurposing by connecting structural similarity of drugs and their side effects to protein – protein interactions. In addition, the integrated network visualization tools of PROMISCUOUS allow researchers to explore and understand the analysis of the interplay between drugs and targets, as well as identify candidates for drug repurposing.

DRAR-CPI server (see "Relevant Websites section") uses the database of 254 active form from 166 drugs with known adverse drug reaction (ADR) and 385 pockets from 353 human protein targets for predicting drug repurposing potential via chemical-protein interactome (CPI). When users submit a drug molecule, the DRAR-CPI server computes the binding energies of this drug with all 385

protein pockets in the database using the DOCK program (Ewing *et al.*, 2001), and then generates its CPI profile. Based on this CPI profile, the server identifies the association scores between the drug and all 166 drugs in the database, and predicts off-target proteins that possibly interact with it. Recently, the DRAR-CPI has been upgraded to DPDR-CPI server (see “Relevant Websites section”) with the larger database of 2515 drugs and 611 human protein targets (Luo *et al.*, 2016). The AutoDock Vina program (Trott and Olson, 2009) is used in the new server for docking of drug molecules with human protein targets to generate CPI profiles.

The e-Drug3D (see “Relevant Websites section”) provides the annotated database of 3D structures from FDA approved drugs as well as commercial sub-structures (fragments) of drugs. This database of 3D structures of drug can be used for virtual screening applications, such as fragment-based drug design and drug repurposing. DrugPredict collects and identifies effect profiles and 3D structures of small molecule drugs (Simon *et al.*, 2012). Using docking calculations, DrugPredict determines interactions of each drug and non-target protein binding sites, which are used for new drug effect predictions. DrugMap Central collects multi-level drug data from various established databases, including drug targets, chemical structures, target-related signaling pathways, FDA and clinical trial information (Fu *et al.*, 2013). DrugMap Central provides online query tool and visualization-based search to support researchers for drug repurposing studies.

PharmDB is an integrated database of drug development, disease indications, associated proteins, and their known interactions (Lee *et al.*, 2012). The Shared Neighborhood Scoring algorithm is developed for PharmDB to identify new indications of known drugs, which can be used for predicting drug repurposing potential. Another database, PharmDB-K offers comprehensive information relating to Traditional Korean Medicine (TKM), associated drugs (compound), disease indication, and protein relationships (Lee *et al.*, 2015). In PharmDB-K, information is organized as a network with five kinds of nodes: TKMs, drugs, diseases, proteins, and side effects. The website also integrates diverse tools to explore TKM-disease, TKM-drug, drug-disease, drug-drug, drug-protein, drug-side effect, disease-protein, and protein-protein relationships by analyzing the network.

RE:fine drugs contains information on 916 drugs, 567 genes and 1770 diseases (Moosavinasab *et al.*, 2016). The database is constructed based on the Transitive Property of Equality between drug-gene and gene-disease pairs of information extracted from previously published datasets (Moosavinasab *et al.*, 2016). Users can explore the database using drug/gene/disease information and identify drug-disease candidates for repurposing. The results can also be sorted based on P-value, odds ratio, literature support, clinical trials, disease name and/or drug name.

Mantra 2.0 maintains information on drugs as a network, with drugs as nodes and edges highlighting communities of drugs sharing similar mode of action (Carrella *et al.*, 2014; Iorio *et al.*, 2010). The network is constructed by exploiting similarities in gene expression profiles following drug treatment (Carrella *et al.*, 2014). Mantra allows users to provide gene expression profiles before and after drug treatment in one or multiple cell types as input. These gene expression profiles are transformed into a drug node and integrated in the drug network, which allows users to inspect its mode of action and repurposing opportunities.

The databases such as repoDB, RepurposeDB, SIDER, SWEETLEAD and DrugBank also have various information on repurposed/approved drugs (see Table 1) that can be used as references for drug repurposing experiments. The repoDB also has information on failed drugs (Brown and Patel, 2017). Information on failed drugs can be useful as there are many drugs that are abandoned after clinical trials due the lack of efficacy for their primary indications, and which possess the same benefits of approved drugs (Novick *et al.*, 2013). SWEETLEAD (Novick *et al.*, 2013) is a highly curated database of chemical structures for the globally approved drugs. It is developed with the objective of providing well curated, high quality information of the known approved drugs for drug repurposing experiments. DrugBank is also known for its expertly curated data on drugs and is the referential drug data source for many well-known databases (Law *et al.*, 2014), such as PDB (Rose *et al.*, 2013), PubChem (NCBI Resource Coordinators, 2013), UniProt (UniProt Consortium, 2013), among others. DrugBank has detailed information on drugs (i.e., chemical, pharmacological and pharmaceutical) and drug targets (i.e., sequence, structure, and pathway) (Law *et al.*, 2014). The latest version of DrugBank (version 5.0.9) has information on 10,505 drugs.

Resources such as DeSigN and Cmap have large collections of drug-induced signatures and they integrate computational tools that facilitate drug repositioning based on genomic screening (see Virtual Screening) (Lee *et al.*, 2017; Lamb, 2006). The details of the databases discussed here are detailed in Table 1.

Computational Tools for Drug Repurposing

Currently, there are two major structure-based categories for drug repurposing by using (i) ligands/compounds similarity and (ii) binding pocket similarity. Computational methods using 1D or 2D representations for compound structures are commonly used in ligand-based virtual screening because chemical molecules are typically represented by 1D fingerprints or 2D molecular formula (Schwartz *et al.*, 2013; Helguera *et al.*, 2008; Hong *et al.*, 2008). However, the 3D structural information of compounds and target proteins as well as their atomic interactions in the 3D space are not captured by 1D and 2D methods. Furthermore, although the 1D and 2D representations of chemical molecules are not similar, these molecules could share biological activities if their 3D shape are similar. Binding affinity between compounds and target proteins is governed by atomic interactions in the 3D space. Therefore, 3D methods have potential to overcome the limitations of 1D and 2D methods and enhance performance for ligand-based virtual screening. In the past, there have been efforts with some degree of success in developing computational methods to identify similarities between the 3D structures of compounds (Schuffenhauer *et al.*, 2000; Kombo *et al.*, 2013; Shin *et al.*, 2015). Recently, we have applied our CLICK algorithm (Nguyen and Madhusudhan, 2011), whose main strength emerges from its unique ability to carry out topology independent comparisons, for comparing 3D structures of compounds.

Table 1 Databases for drug repurposing^a

Databases	Key features	Website
PROMISCOUS von Eichborn <i>et al.</i> (2011)	- Contains information on 25,000 drugs (including withdrawn and experimental drugs), their side effects and targets. - Users can explore the database based on drugs, their targets, side effects or, metabolic and signaling pathways.	http://bioinformatics.charite.de/promiscuous
DPDR-CPI Luo <i>et al.</i> (2016)	- Contains information on 2515 drugs. - Predicts off-targets and potential indications for the small molecule input from the user.	https://cpi.bio-x.cn/dpdr/
e-Drug3D Pihan <i>et al.</i> (2012)	- Contains ready to screen SD files of drugs and commercial drug fragments. - Contains information on 1852 molecular structures.	http://chemoinfo.ipmc.cnrs.fr/MOLDB/
DrugPredict Simon <i>et al.</i> (2012)	- Contains information on 100,000 small molecule compounds including 1200 approved drugs. - Users can explore the database based on drugs/any desired effects.	http://www.drugpredict.com/
PharmDB Lee <i>et al.</i> (2012)	Contains information on 11,792 drugs, 38,057 proteins and 6607 diseases and their relationship.	http://www.i-pharm.org/
PharmDB-K Lee <i>et al.</i> (2015)	- Provides information on Traditional Korean Medicine (TKM). - Contains information on 262 TKMs, 7815 drugs, 3721 diseases, 32,373 proteins, and 1887 side effects.	http://pharmdb-k.org/
RE:fine drugs Moosavinasab <i>et al.</i> (2016)	- Contains information on 916 drugs, their target genes and associated diseases. - Users can explore the database based on drug, indication or gene symbol.	http://drug-repurposing.nationwidechildrens.org
Mantra 2.0 Carrella <i>et al.</i> (2014)	- Provides the users insights on mode of action of drugs by comparing drug-induced signatures. - Contains information on 1309 small molecules.	http://mantra.tigem.it/
repoDB Brown and Patel (2017)	- Contains information on 1571 drugs (including approved and failed drugs), their indications and clinical trial status. - Users can explore the database based on drug/disease information.	http://apps.chiragjpgroup.org/repoDB/
RepurposeDB Shameer <i>et al.</i> (2017)	- Contains information on 253 repurposed drugs and their indications. - Users can explore the database based on drug/disease information, side effects, drug targets or pathways. - Facilitates chemical similarity search for new compounds and sequence similarity search for new protein-drugs against RepurposeDB. - Allows drug repurposing investigators to report their results to the community.	http://repurposedb.dudleylab.org/
SIDER Kuhn <i>et al.</i> (2016)	- Contains information on 1430 drugs and their side effects. - Users can explore the database based on drugs/side effect information.	http://sideeffects.embl.de/
SWEETLEAD Novick <i>et al.</i> (2013)	- Contains accurate chemical structures of 4442 compounds (including approved drugs and non-toxic chemicals). - The database can be downloaded and used for virtual screening/drug repurposing campaigns.	https://simtk.org/home/sweetlead
DrugBank 5.0.9 Law <i>et al.</i> (2014)	- Contains information on 10,505 drugs (including 1733 approved small molecule drugs, 870 approved biotech drugs, 105 nutraceuticals and over 5025 experimental drugs). - Provides detailed information on drugs (i.e., chemical, pharmacological and pharmaceutical) and drug targets (i.e., sequence, structure, and pathway) information.	https://www.drugbank.ca/
DeSigN Lee <i>et al.</i> (2017)	- Contains information on cancer-associated gene expression profiles from 140 drugs. - Allows drug repositioning based on genomic screening.	http://design.cancerresearch.my/
Cmap Lamb (2006)	- Contains gene expression profiles from 5000 small molecule compounds. - Allows drug repositioning based on genomic screening.	https://www.broadinstitute.org/connectivity-map-cmap

^aSome relevant databases for drug repurposing, their key features and websites are listed as of 9th November 2017. The table lists only databases having active websites.

It is well understood that drugs bind to their protein targets because of complementarity in shapes of ligands fitting into their binding pocket. However, the shape of a particular binding pocket on a target is possibly found in some other proteins, given the diversity of protein shapes in a cell. This will inevitably lead to the binding of the drug to other proteins (off-target proteins) possessing structurally similar binding pockets (John Fox *et al.*, 2016). Hence, the discovery of the off-target proteins of a drug can lead to further use of this drug for additional targets in disease treatment. Clearly, the discovery of the off-target proteins will rely on an accurate determination of similarity of binding pocket. A major effort towards developing tools to search for such

similarities has been focused on local structural alignment approaches (Shulman-Peleg *et al.*, 2007; Konc and Janežič, 2010). One such effort is the CLICK method (Nguyen *et al.*, 2011) that performs 3D structural superposition on pairs of structures based on similarity of local structural packing, and thus is capable of aligning structures with dissimilar conformations or even molecular types (Nguyen and Verma, 2015; Nguyen *et al.*, 2017b). These unique properties make CLICK particularly ideal for comparing the similarity of binding pocket (Lukman *et al.*, 2017; Nguyen *et al.*, 2017a).

In addition, investigation of complex interactions between drugs and diseases is crucial for new drug-disease association discovery and drug repurposing (Yang *et al.*, 2014). However, it is difficult to identify the comprehensive interactions of drugs and diseases because of the polypharmacological profiles of drugs (Reddy and Zhang, 2013) and complex diseases induced by genes' collective abnormalities (Wu *et al.*, 2013). Disease-based computational methods have been developed to identify the interactions between drugs and diseases by using shared molecular pathology, associative indication transfer, and side effect similarity (Dudley *et al.*, 2011a,b). Recently, computational methods using pathway-based Bayesian inference (Pratanwanich and Lió, 2014), network propagation (Huang *et al.*, 2013), and network-based inference (Cheng *et al.*, 2012a,b) have been applied for investigating drug-disease interactions. In these methods, the network of drug – Target – Pathway – Gene – Disease is constructed from multi-level interactions of drugs and diseases integrated from known databases. Next step, the interaction scores of drugs and diseases are computed by evaluating effects of drugs on multiple targets and pathways (Yang *et al.*, 2014). The new potential repurposing of the existing drug is then determined from the network of drug targets and disease-related genes (Pratanwanich and Lió, 2014).

Virtual Screenings: Genomic Screenings, High-Throughput Screenings

Virtual screening can be defined as a set of computer methods that analyse compounds in large databases in order to identify a smaller number of them for biological testing (Sottriffer, 2011). Virtual high-throughput screening (vHTS) and genomic screening are two virtual screening techniques that can be employed for drug repurposing. vHTS is the computational analogue of *in vitro* high-throughput screening (HTS). vHTS involves screening of large compound libraries to identify compounds/ligands that can bind to the biological target of interest with high affinity (Shoichet, 2004). Using vHTS, large collections of known compounds can be screened to identify their applicability to treat a new disease.

There are many public databases that can be employed for vHTS (Cheng *et al.*, 2012a,b). For example, ZINC (zinc.docking.org) is a public database that contains over twenty million commercially available compounds in biologically relevant representations, that can be downloaded in ready-to-dock formats (Irwin *et al.*, 2012). It is also possible to download the database in fractions based on physical properties, purchasability, and vendors, among other attributes. In a previous study, we have employed vHTS of 'Drugs Now' subset (a subset of 10,639,555 compounds having drug-like properties such as adequate chemical stability, metabolic stability, minimal toxic effects and oral bioavailability Lipinski, 2000) from the ZINC database, for the identification of inhibitors of aberrant proteins, such as (1) Ras proteins that are implicated in diverse cancers and developmental diseases (Grant *et al.*, 2011), (2) protein tyrosine phosphatase 1B that is associated with diabetes, obesity, cancers, and neurodegenerative disorders (Kumar *et al.*, 2018). In these examples, the inhibitors act allosterically. Indeed, drug repurposing efforts will generally be more beneficial if the drug binding sites are allosteric rather than orthosteric (Nussinov and Tsai, 2012).

vHTS can be classified as structure-based and ligand-based approaches (Fig. 1). Structure-based screening is employed when the three-dimensional structure of a disease-associated target is known. When the target structure is unknown and its prediction is challenging, ligand-based screening is employed. The objective of both these approaches is the same, i.e., to select a smaller subset of compounds from larger libraries and rank them using some scoring criteria, to be further used for experimental testing of their biological activity.

Structure-based screening involves molecular docking of candidate ligands from the library into a protein (target) followed by applying a scoring function (Liang *et al.*, 2009; Deng *et al.*, 2004; Amari *et al.*, 2006) to estimate the likelihood that the ligand will bind to the protein (Kroemer, 2007; Wang *et al.*, 2000). Since the computational cost of the docking is directly proportional to the number of compounds, pre-filtering of large libraries is highly desirable (Radusky *et al.*, 2017). Candidate compounds from the libraries can be filtered based on their drug-like properties (Lipinski, 2000; Lipinski *et al.*, 2001). Target-specific filters can also be used for creating focused libraries (Gozalbes *et al.*, 2008; Sage *et al.*, 2011). For example, more recently Radusky *et al.* developed 'LigQ' server (see "Relevant Websites section") that can assist in various steps of virtual screening (Radusky *et al.*, 2017). The webserver can be employed in initial stages of virtual screening to identify potential binders for targets from large databases. Enriching compound libraries in these ways can greatly reduce the computational cost of subsequent docking. The target and ligand structures also need to be prepared before docking by assigning proper tautomeric, stereoisomeric, and protonation states, among others (Rapp *et al.*, 2009; ten Brink and Exner, 2010). After pre-processing of target and compound library, docking is performed.

Many docking programs are available to computationally model the ligand – Target interaction. Some examples of docking programs in vHTS are listed in Table 2. These docking programs generally involve a search algorithm that searches the conformational space to find docking poses and a scoring function to predict the affinity of the ligand with the target in that pose (Sliwoski *et al.*, 2014). The candidate ligands that are selected through docking are then post-processed by examining their binding scores, interactions, and binding pose, among others, based on which a smaller number of compounds are selected for experimental testing (Lionta *et al.*, 2014). Numerous success stories have been reported in drug repurposing through the use of structure-based screening (Palos *et al.*, 2017; Lukman *et al.*, 2017; Bi *et al.*, 2017; Sahoo *et al.*, 2016). For example, Chan *et al.* (2011) identified an FDA approved drug methylene blue from a database of over 3000 compounds using structure-based screening to

Fig. 1 Virtual high-throughput screening (vHTS) and its classifications. In vHTS, large compound databases are screened to identify candidate ligands for experimental testing. Pre-filtering of compounds in the databases is usually done before screening. vHTS can be classified as structure-based screening and ligand-based screening. Structure-based screening involves protein-ligand docking. Ligand-based screening can be classified as similarity-based approaches, pharmacophore mapping and classification techniques.

Note: Modified from Cheng, T., Li, Q., Zhou, Z., Wang, Y., Bryant, S.H., 2012. Structure-based virtual screening for drug discovery: A problem-centric review. *AAPS J.* 14, 133–141. Available from: <https://doi.org/10.1208/s12248-012-9322-0>.

stabilize the c-myc Pu27 G-quadruplex DNA that are putatively present in the promoter regions of oncogenes from the human genome Chan *et al.* (2011). Li *et al.* repositioned two organohalogen drugs to inhibit B-Raf protein kinase which is mutated in a broad range of human cancers by developing a docking program that takes into account halogen bond interactions Li *et al.* (2016).

Ligand-based screening makes use of the knowledge of ligands that binds to the target of interest for screening, based on the notion that ligands interacting with the same target show same structural or physicochemical properties. Ligand-based screening can be classified as molecular similarity-based approaches, pharmacophore mapping and compound classification techniques (Acharya *et al.*, 2011). Molecular similarity-based approaches usually employ 2D/3D chemical similarity analysis of the active ligand structure against a library of molecules (Bajorath, 2011; Bologna *et al.*, 2006; Lindert *et al.*, 2013) to identify chemically similar compounds. Molecular descriptors such as fingerprints derived from molecular graphs (2D) or conformers (3D)

(Cereto-Massagué *et al.*, 2015), topological indices (Fukunishi and Nakamura, 2009), molecular fields (Cheeseright *et al.*, 2006), and others, can be used for the similarity search of ligands. As a measure of comparison, similarity between molecular descriptors of two structures is quantified using a similarity coefficient. Most frequently, Tanimoto coefficient is used, which is defined as $N_{ab}/N_a + N_b - N_{ab}$, where N_a and N_b are the number of features in the fingerprint of compounds “a” and “b”, respectively and N_{ab} is the number of features in fingerprints of both the compounds.

Pharmacophore mapping relies on the knowledge of molecular features (such as hydrogen bonds, charged interactions, hydrophobic and aromatic contacts) that are necessary for molecular recognition of a ligand by a target. By using the knowledge about the structurally diverse ligands that bind to a target, a model of target/pharmacophore can be built and can be employed for rapid screening of large databases (Sukumar and Das, 2011; Sun, 2008; Lin, 2000; Patel *et al.*, 2002; Pan *et al.*, 2013; Goodford, 1985). The quality of fitting the ligand into the pharmacophore query is more commonly expressed by the root mean square deviation (RMSD) between the features of the query and atoms of the molecule (Langer and Hoffmann, 2006).

Compound classification techniques include clustering techniques (such as PCA), partitioning techniques (such as recursive partitioning), and machine learning approaches (such as support vector machines, decision trees, k-nearest neighbours, naïve Bayesian methods, and artificial neural networks). The goal of this approach is to predict the activity of the compound based on models derived from the training set as well as the ranking of the database compounds based on the probability of their activity (Melville *et al.*, 2009; Bajorath, 2001).

As in structure-based screening, pre-filtering of compound libraries in accordance with the goals and constraints of the study is also beneficial in ligand-based screening (Yan *et al.*, 2016; Glaab, 2016). Many recent works have reported the usage of ligand-based screening for drug repurposing (Paz *et al.*, 2017; Keiser *et al.*, 2009; Vasudevan *et al.*, 2012; Crisan *et al.*, 2017). For example, Crisan *et al.* (2017) employed pharmacophore model for virtual screening and identification of known drugs that could inhibit glycogen synthase kinase-3 (GSK-3) which is involved in diseases such as psychiatric and neurological diseases, inflammatory diseases, and cancer. Anighoro *et al.* (2015) employed 2D ligand-based similarity analysis of ChEMBL database (see “Relevant Websites section”) combined with support vector machine models and analysis of 3D structural information of ligand-target complexes, and identified a promising set of target combinations and associated ligands within the Hsp90 interactome, which contains several targets of key importance in cancer Anighoro *et al.* (2015).

A limitation of vHTS is that, it cannot identify the full spectrum of targets that a small molecule may be hitting, as a result of which drugs can elicit undesirable off-target effects. To overcome this drawback, vHTS can be integrated with deep molecular characterization and network analysis (Leung *et al.*, 2013). Network models allow integration of data from various information sources, capturing both quantitative and qualitative relationships between entities and the presence or absence of an interaction (Paolini *et al.*, 2006). For example connecting drugs by side effect similarity can provide insights into the drug’s side effects and may also allow prediction of novel off-targets (Campillos *et al.*, 2008).

Often, structure-based screening requires thorough knowledge of the 3D structures of targets and their mechanisms at atomistic levels. Methods to resolve the 3D structures, such as X-ray crystallography and nuclear magnetic resonance method, are time- and cost-consuming. Atomistic-level of target mechanisms, observed through molecular dynamics simulations (Lukman *et al.*, 2012), can be very critical for drug repurposing. When we do not know the underlying mechanism associated with a disease, genomic screening methods are particularly useful. In such cases candidate ligands can be predicted using the molecular signature (i.e., significantly up and down regulated genes) of the disease that is generated through the analysis of differences in genomic patterns from disease affected and unaffected individuals. The corresponding signature of differential gene expression can be compared with differential gene expression signature induced by drugs, (i.e., changes brought about in the genomic patterns after exposure to a drug). If both the disease-associated and drug-induced signatures are sufficiently negatively correlated (i.e., the effects induced by drugs are opposite to the effects associated with the disease), then the drug may be able to revert the disease-associated signature and hence it can be considered as candidate for repurposing (Sirota *et al.*, 2011). Another approach employed in genomic screening is to look for drugs that can induce similar effects in gene expressions, by comparing the drug-induced signatures. It can be hypothesized that two drugs that can induce the same changes share similar mode of action/therapeutic application (Iorio *et al.*, 2010). Candidate ligands are thus identified in genomic screening by their direct or inverse correlation to the query signature (Fig. 2).

Publicly available databases such as Cmap (see “Relevant Websites section”) (Lamb, 2006, 2007) and LINCS (see “Relevant Websites section”) (Duan *et al.*, 2014) have thousands of gene signatures representing a diverse range of FDA approved drugs. The data from these databases can be integrated with functional genomics databases like NCBI-GEO (see “Relevant Websites section”) (Edgar *et al.*, 2002) and ArrayExpress (see “Relevant Websites section”) (Brazma *et al.*, 2003) for drug repositioning studies using genomic screening. Many previous studies have shown the benefits of employing Cmap data in drug repositioning (Iorio *et al.*, 2009, 2010; Napolitano *et al.*, 2013; Silberberg *et al.*, 2012; Parkkinen and Kaski, 2014; Yu *et al.*, 2015; Jadamba and Shin, 2016). For example, Dudley *et al.* employed Cmap data for repurposing topiramate, an anticonvulsant drug for treating inflammatory bowel disease (IBD) (Dudley *et al.*, 2011a,b). They employed gene expression data from NCBI-GEO and created a gene expression signature for IBD using the Significance Analysis of Microarrays (SAM) software (see “Relevant Websites section”) (Tusher *et al.*, 2001). Then they systematically compared the signature to drug-induced signatures obtained from the Cmap. Drugs that are anti-correlated to the disease were selected based on their therapeutic scores that were computed based on a randomization algorithm.

Although genomic screening methods are advantageous in studying genome-wide patterns of how drugs are changing biological systems, there are still some limitations. Some portion of the genes that show significant expression differences in the drug-induced signatures, may be produced by drug side effects (Jadamba and Shin, 2016). Furthermore, the differential gene expression induced by drugs represents only a small subset of biological pathway (Jadamba and Shin, 2016). So as suggested in vHTS, the integration of

Fig. 2 Genomic screening for drug repurposing. In genomic screening approach, the query signature (either disease-associated or drug-induced signature) is compared with target signatures (drug-induced signatures) and their inverse or direct correlations are analyzed based on which the candidate ligands are chosen for experimental testing.

network models with genomic screening methods can provide better understanding of the drug-disease relationship. For example, more recently, [Mulas *et al.* \(2017\)](#) employed a network-based differential analysis of gene expression profiles to identify modes of actions of drugs. The proposed method is able to identify pathways significantly associated with the drug-induced signatures.

There are also many reports in literature of the combined use of the above-mentioned methods for drug repurposing studies. For example, [Han *et al.* \(2017\)](#) have recently identified a known drug that could inhibit Human enterovirus 71 (EV71) that can cause hand, foot and mouth disease. They have constructed EV71 protein interaction network and identified drugs that can target the interacting proteins. They used Cmap for the evaluation of drug influences on the genomic signatures of targets. Similarly, genomic screening methods can also be employed following vHTS for evaluating the candidate drugs. [Phatak *et al.*](#) have employed a multi-modal approach to repurpose existing drugs against ACK1, a cancer target significantly over expressed in breast and prostate cancers during their progression ([Phatak and Zhang, 2013](#)). They used structure-based screening followed by a pharmacophore-guided method to select a set of drugs as potential ACK1 inhibitors. To compensate for the limitations of the docking methods employed in their study, they employed different metrics based on chemical similarity, genomic similarity and drug-target bipartite graph to evaluate if complementary results can be obtained.

Since each screening method described above has its own field of applicability, drawbacks and limitations, integration of multiple methods described above may be beneficial for drug repurposing.

Challenges and Possible Solutions

Despite the potential benefits of drug repurposing, the pharmaceutical industry is less interested to find new uses of old drugs. One of the major barriers that hinders the development of repurposed drugs is lack of data exclusivity ([Kato *et al.*, 2015](#)). The period of

data exclusivity for repurposed drugs is often insufficient for the pharmaceutical industries for making a reasonable profit (Shineman *et al.*, 2014; Gaudry, 2011). Moreover, commercial returns for a newly formulated product depends on the coverage and reimbursement provided for it by a payer such as a third party private or government insurer (Shineman *et al.*, 2014). When a generic drug is repurposed for a new indication through a new formulation, the payer is unlikely to provide the coverage unless they accept its clinical benefit over the generic drug (Shineman *et al.*, 2014). All these reasons withhold the pharmaceutical industry from investing in drug repurposing.

To tackle these problems, non-profit organizations and governments can collaborate and take the initiatives to accelerate drug repurposing. The government can take actions to extend the period of data exclusivity for repurposed drugs (Shineman *et al.*, 2014). Additionally, the government can offer meaningful incentives to the pharmaceutical companies for drug repurposing (Kato *et al.*, 2015). Governments and non-profit organizations should work together to create awareness at the organizational and individual level to establish the notion that patient-relevant outcomes should ultimately drive the definition of value for drugs (Shineman *et al.*, 2014). Moreover, research done at the academic institutions can also be motivational for the pharmaceutical industries to repurpose old drugs. Such research can be funded and an infrastructure can be created to co-ordinate the research interests of academic institutions and the pharmaceutical companies (Beachy *et al.*, 2014).

Additionally, the interactions between drugs and their respective target(s) are influenced by the target's structure which is not static, but dynamic (Lukman *et al.*, 2014). Considering the intrinsic dynamics of the target structure, i.e., the structure of proteins where drugs can bind to and regulate them, efforts to identify existing and novel binding sites from multiple structures of the same and/or related protein structures, for example through homology modeling, molecular dynamics simulations, and clustering approaches (Sim *et al.*, 2013), have been undertaken for several targets. Examples of the targets are Bromo and Extra terminal (BET) proteins (Lukman *et al.*, 2015a), insulin receptor (Lukman *et al.*, 2015b), and insulin-degrading enzyme (Lukman, 2016). Identification of binding sites are critical for docking and ensemble docking (Lionta *et al.*, 2014) of known drugs that was previously unknown for affecting a particular target of interest, yet have minimal toxicity.

Transcriptome Analysis

Anuj Srivastava, Joshy George, and Radha KM Karuturi, The Jackson Laboratory, CT, United States

© 2019 Elsevier Inc. All rights reserved.

Introduction

Transcriptome is a collection of all RNA molecules in one cell or a population of cells. RNA has long been at the center of molecular biology and its importance had been established in a series of paradigm-shifting discoveries over the last 60–70 years. Prior to 1940s, it was considered that proteins carried out both genetic information and enzymatic catalytic function of cells. In the 1950s, Crick published the central dogma that showed RNA served as an intermediary molecule during the transfer of genetic information of proteins (Crick, 1958). For many years, after the establishment of the central dogma, it was believed that RNA molecules come in 3 flavors (rRNA, tRNA, and mRNA) and their primary function involved protein syntheses. Later in the 1980s, several other types of RNAs including uridine (U)-rich U RNAs were discovered; in the same time period, Cech and Altman, studying the splicing in *Tetrahymena thermophile* and bacterial RNase P complex, respectively, concluded that RNA had catalytic functions as ribozymes (Cech *et al.*, 1983). In the 1990s, Ambros and colleagues (Lee *et al.*, 1993) showed the first evidence of RNA mediated regulation (by microRNA or miRNA) in *Caenorhabditis elegans* development and thus establishing three primary roles of RNAs: (i) Being the genetic material (ii) act as ribozymes (iii) and regulate other macromolecular processes. Hence, both mRNAs or messenger RNAs (protein-coding RNAs) and non-coding RNAs or ncRNAs (do not code proteins) are of interest in a variety of studies. The ncRNAs of particular interest are miRNAs which are short ncRNAs that regulate the lifetime of mRNAs; and, lncRNAs or long non-coding RNAs which are ≥ 200 nucleotides long, regulate the gene expression and also take part in a broad range of cellular & developmental processes.

The type and quantity of genes transcribed is dependent on the cell-type and its environment, and is tightly regulated. Disruptions to this regulatory process is often the cause of several diseases. Being intermediary between DNA and proteome as well as being molecules of regulatory role, understanding the variations in the transcriptome of a cell in response to the changes in the function and environment of the cell is critical to understanding the regulatory mechanisms pertinent to the mechanistic understanding of the development and disease. Thus, the composition of transcriptome is often used as a proxy for cellular functional status.

Our understanding of the transcriptome has been largely enabled by the advancement in technology. In the late 90's, microarrays could be used to profile the transcriptome of a population of cells. This technology essentially was used to measure the average expression level for each gene across a large population of input cells. However, microarrays detect only known RNAs, so they can't be used for discovery. In addition, background hybridization interferes with detection of low-level expression and probe saturation causes variation in highly expressed genes undetected. Recent advances in sequencing technology have made it possible to quantify the transcriptome of a population of cells by sequencing (RNA-seq or bulk RNA-seq). The number of reads mapping to a gene is a measure of the transcriptional level of that gene. RNA-seq, while being more precise than array based methods, it also offers simultaneous transcript discovery and quantification. Bulk RNA-sequencing enabled us to compare the transcriptome across different samples and had significant input into our understanding of several disease processes including cancer. In 2009 (Tang *et al.*, 2009), a new method was proposed to profile transcriptome from an individual cell. This technology is now referred to as single-cell RNA-seq (scRNA-seq) and has improved our understanding of the heterogeneity present in the otherwise homogeneous tissues. scRNA-seq allows to study new biological questions in which cell-specific changes in transcriptome are important and these include, cell type identification, heterogeneity of cell responses, stochasticity of gene expression and inference of gene regulatory networks across the cells.

Thus, in this article, we describe the guidelines for experimental design, data quality control and computational methods that can be used to derive biological insights from bulk RNA-seq data for mRNA, miRNA, and lncRNA; and scRNA-seq data. The procedures described in this article have been applied in multitude of studies such as Chow *et al.* (2017); George *et al.* (2016); Ucar *et al.* (2017).

Experimental Design, Data Processing & Quality Assessment

Experimental design is very important, though often neglected, step of the project. A well-designed experiment will have sufficient power to address the biological question of interest. A good experimental design in RNA-seq experiment considers library types (single end/paired end), number of reads or sequencing depth and number of replicates per condition. If the goal of the experiment does not involve the novel isoform discovery then single end data should serve the purpose. If the project requires only quantification of gene expression, as suggested by the ENCODE (encyclopedia of DNA elements) study, ~ 36 million mapped reads would be sufficient to accurately quantify the abundance of 80% of genes (Sims *et al.*, 2014). It's also been noted that to detect the novel and rare isoforms, ~ 200 million paired-end reads will be required in human cells.

Adding control sequences: It's important to consider including exogenous reference transcripts ('spike-ins') (Chen *et al.*, 2015) that are useful both for quality control and for library-size normalization. The *External RNA control consortium (ERCC) spike-in*

Fig. 1 Schematic for mRNA-seq quantification pipeline.

control mix consists of pre-formulated set of 96 polyadenylated transcripts with varying GC content and length can be used for this purpose.

Sample size estimation: Besides library preparation, estimation of the number of samples per condition is also important for a reliable identification of transcripts relevant to the study. Statistical power to detect differentially expressed genes (DEGs) varies with effect size, sequencing depth and the number of samples per condition. Analysis of data sets from several studies indicates the need for negative binomial distribution to account for the over-dispersion mainly caused by natural biological variation present in RNA-seq studies (Anders and Huber, 2010; Robinson and Oshlack, 2010). The complexity of this distribution makes it difficult to arrive at an analytical solution for power analysis and sample size estimation (Pham and Jimenez, 2012). Other issues that complicate the power estimation include multiple hypotheses correction, techniques used to estimate dispersion, and normalization methods used. Therefore, numerical methods such as Monte Carlo simulations have often been employed to analyze and estimate the sample size required for RNA-seq studies (Ching et al., 2014). However, with fixed cost and limited resources for the experiment, reducing the number of reads per sample while increasing the number of samples will yield better results for DEG analysis. As a general rule, at least three samples per condition is recommended.

Batch Effect is defined as a non-biological source of the signal that is introduced into the data and that can confound with the biological signal. The batch effect is typically consistent across transcripts, exons or genes among samples in a batch and so may lead to gross errors in the calculation of statistical significance, estimation of effect sizes and other statistical measures. Several studies have noticed batch effects due to reagent batch and sequencing dates. Therefore, it is important to design RNA-seq experiments to minimize the effect of technical noise due to batch effects. However, batch effects cannot be completely eliminated due to the constraints of sample availability or other logistical limitations. In such situations, randomization of samples across library preparation batches and lanes is highly recommended to avoid technical factors completely confounding with the experimental conditions. For example, an experiment with all treatment samples are sequenced in one batch while the control samples are sequenced in another batch is difficult to analyze. A few examples of desirable and undesirable experimental designs are depicted in Fig. 2:

The processing of transcriptomic data (schematics are provided in Figs. 1, 10 and 11), RNA-seq data precisely, can be divided into 3 major steps.

- (1) **Quality control (QC):** Quality control (QC) is a critical step in both bulk and single-cell RNA-seq data analysis. For bulk RNA-seq, the QC steps include assessment of RNA quality and samples with inadequate quality will not be sequenced. Quality of raw sequencing data will be assessed based on the number of reads and the read quality scores. Examples for good and poor-

Batch	1	1	1	1	1	1	1
Experiment	T	T	T	T	C	C	C

(a) Most desirable design.
All samples are
processed in one batch
i.e. no batch effects.

Batch	1	1	2	2	1	2	2
Experiment	T	T	T	T	C	C	C

(b) Desirable design if batches are
inevitable. Experimental
conditions are not completely
confounded with batches.

Batch	1	1	1	2	2	2	2
Experiment	T	T	T	C	C	C	C

(c) Undesirable design,
batches confounded
completely with
experimental conditions.

Distribution along the base position of reads

(b) Per Sequence Quality (Phred score)
Distribution

Fig. 3 Quality assessment of RNA-seq libraries by checking.

quality data are shown in **Fig. 3**. Finally, the mapping quality score which is the probability that the read is misplaced after the alignment of the read, provides a measure of the overall quality of the data.

The raw read quality estimation involves determining per base quality and per sequence quality, identification of duplicates, GC content, and presence of adaptors/over-represented sequences (see **Fig. 4** for an example). FastQC (for Illumina: see “Relevant Websites section”) and NGSQC (platform independent) (Dai *et al.*, 2010) are two popular tools, that provides the quick diagnostics of an NGS library. Removal of poor quality reads & bases, trimming of adaptors can be performed via FASTX-Toolkit (see “Relevant Websites section”) and Trimmomatic (Bolger *et al.*, 2014).

In case of scRNA-seq data, distinguishing biological heterogeneity from technical artifacts makes it much more difficult to assess the quality. The limited amount of RNA available from a single cell makes it difficult to assess the quality of RNA prior to sequencing. Previous studies have used the expression levels of housekeeping genes. But this approach is not used anymore after the demonstration that they are highly variable and associated with cell-types (Oyulu *et al.*, 2012). Often the number of genes detected and the mapping rates are used as QC measures to remove low-quality cells prior to downstream analysis. The proportion of reads mapping to the mitochondrial genes is an indication of cells that are undergoing apoptosis and can be used to remove low-quality cells (Jiang *et al.*, 2016).

- (2) **Mapping:** Reads from an RNA-seq experiment can be mapped to the genome or a known transcriptome. Mapping to the genome is performed if the goal of the experiment includes identification of novel isoforms. For a typical high-quality human sample library, >70% of mapping rate to human genome is expected. TopHat2 (Kim *et al.*, 2013) and STAR (Dobin *et al.*, 2013) are popular algorithms (spliced aware mapper i.e., accounting for splice junctions during mapping) for genome mapping. Whereas, the transcriptome based mapping can be performed by bowtie2/bwa (Langmead and Salzberg, 2012; Li and Durbin, 2010). Transcriptome based mapping yields lower percentage of reads mapped due to lack of sequences of unannotated transcripts. When a reference genome is not available (for non-model organisms) or is incomplete, then *de novo* transcriptome assembly should be performed. Trinity (Grabherr *et al.*, 2011), Oases (Schulz *et al.*, 2012) and SOAP *denovo*-Trans (Xie *et al.*, 2014) are some of the popular algorithms for transcriptome assembly. Longer reads or paired-end reads will aid in the *de novo* assembly. It is recommended to combine all the reads from multiple samples together and then do the combined assembly to generate the

Fig. 4 K-mer and Duplication rate assessment.

Fig. 5 Schematic of bulk sample analysis.

reference set of contigs. These reference contigs can be used for mapping, expression quantification, and comparison across different groups.

- (3) **Quantification:** The important step in RNA-seq data analysis is to estimate gene and transcript abundance. *HTSeq* (Anders *et al.*, 2015) or *featureCounts* (Liao *et al.*, 2014) quantify the abundance by aggregating the number of mapped reads in each exon (determined by Gene Transfer Format [GTF] file), as desired. In addition to aggregating the raw counts, various per sample normalization methods have been developed that accounts for feature-length and library sizes. RPKM (reads per kilobase of exon model per million reads), FPKM (Fragment per kilobase of exon model per million reads) and TPM (Transcript Per Million) are common measures of expression provided by various analysis tools: cufflinks (Trapnell *et al.*, 2010), RSEM (Li and Dewey, 2011), eXpress (Roberts and Pachter, 2013) and Kallisto (Bray *et al.*, 2016). FPKM is used for paired-end read sequencing and RPKM for single-end reads. Whereas TPM, unlike RPKM, skips normalization for gene length after sequencing depth normalization. It makes the sum of all TPMs in all samples same and aid in the comparison of expression profiles among different samples. Transcript abundance is computed as average of normalized abundance of exons in the transcript.

Bulk Transcriptomic Analysis

Bulk sample analysis is a common feature of all experimental designs involving RNA-seq. Its primary aim is to identify genes and gene modules associated with biologically relevant structure in samples e.g., treated vs control samples, tumors of varying clinical attributes, samples of different cellular states, etc. The schematic in Fig. 5 captures the core steps in bulk transcriptome analysis. Each step after the data preprocessing step is described below.

Differential Expression Analysis

A typical RNA-seq study may involve analysis of the impact of one or more factors relevant to the study on the transcriptome, the identification of DEGs. For example, several clinical conditions can affect genes' expression in a patient sample, multiple biological conditions such as cell cycle phase and gene knock-outs can affect the expression of genes in the associated pathways. A factor, representing a biological or a clinical condition, may be categorical with 2 or more levels, or real-valued.

From statistics point of view, the study designs can be classified into three categories: (1) Single factor, 2-level design, (2) single factor, multi-level design, and (3) multi-factor design. Though the analytical approaches used for multi-factor designs are applicable

for the single factor designs, well-tailored methods that may yield better results in sensitivity and specificity are available for the single factor designs. Hence, we will discuss the methods for all three cases separately. The popularly used statistical packages LIMMA (Ritchie *et al.*, 2015), edgeR (Robinson *et al.*, 2010) and DESeq (Anders and Huber, 2010) offer options for all these cases.

Single factor differential expression analysis

In single factor differential expression analysis, the factor takes two or more discrete levels or continuous valued. For example, the factors could be oestrogen receptor (ER) status (ER+ vs ER−, a 2-level factor), p53 mutation status (p53+ vs. p53−, a 2-level factor), histological grade of the tumor (Grade1, Grade2 and Grade 3; a multi-level factor), treatment response (continuous valued in terms of dosage) or any other factor of interest. If the expression of a gene is significantly different for any level of the factor relative to the other levels, the gene will be identified to be DEG.

2-Level single factor DEG analysis

A 2-level differential expression can be analyzed using t-test and Mann–Whitney–Wilcoxon test (Kanji, 1993). Each level of the factor is treated as a group. However, they are not suitable for designs of small sample sizes of less than 10 per group. In such cases, empirical Bayes methods such as LIMMA, edgeR, or DESeq are to be used.

Multi-level single factor DEG analysis

While being applicable, it is not optimal to use 2-level DEG analysis methods to multi-level DEG analysis, owing to $K(K-1)/2$ tests needed for each gene for K-levels. Therefore, multi-level DEG analysis is performed by ANOVA and Kruskal–Wallis tests (Kanji, 1993) for large sample size designs such as large disease cohorts. However, the multi-group option available in the empirical Bayes methods (LIMMA, edgeR and DESeq) needs to be used for typical designs of sample sizes < 10 per group. All these methods test whether there are any statistically significant differences between the means of any one of the group compared to the remaining groups.

Multi-factor differential expression analysis

To decipher the effects of multiple factors, a multivariate or multi-factor analysis will be performed using linear models and generalized linear models (Dobson, 1990). One may use generalized linear models if the errors are not normally distributed but belong to one of the members of the exponential family of distributions. In this case, all samples are treated to belong to one group and the model accounts for the sample characteristics by their attributes. For example, Miller *et al.* (2005) used a linear model to identify p53 mutation specific changes among expression of nearly 30,000 genes using a cohort of > 250 tumors. Expression of a gene is modeled as a combination of *tumor grade*, *ER status*, and *p53 mutation status*. The statistical significance of the estimated parameters of the linear model was evaluated using ANOVA procedure. The genes were ranked by the coefficient of the factor *p53 status* and the top genes were selected to have been affected by p53 mutation specifically.

Deconvolving batch effects

It is important to remove batch effects prior to downstream analysis of data using batch effect removal methods (Leek, 2014). The known batch effects can also be dealt by COMBAT (Johnson *et al.*, 2007) analysis or by incorporating the known batch factors as independent variables in multi-factor differential expression analysis. The unknown batch effects can be identified by whole transcriptome clustering of samples or Surrogate Variable Analysis (SVA) (Leek *et al.*, 2012). However, the observations have to be carefully interpreted for their biological relevance in the data before correcting for them. The more complicated situation is when the batch is completely confounded with that of the biological factor of interest (Fig. 2(c)). Though it is most undesirable, DEGs can be identified if the biological effect is significantly stronger than the batch effect on the gene expression measurements. In such a case, one can use iPLR (Li *et al.*, 2012), as was applied to identify DEGs in batch confounded analysis in this publication, for a better estimate of false discovery rate (FDR) of differential expression followed by effect size filtering.

False discovery rate (FDR) assessment

A critical step towards choosing the right set of differentially expressed genes is the assessment of false discovery rate. The popular differential expression analysis packages such as LIMMA and DESeq provide estimates of local and global FDR. However, the distribution of p-values needs to be examined, see Fig. 6(A) for ideal or theoretical distribution. However, it is common to see the distributions shown in Fig. 6(B–D). FDR estimates can be improved by using *fdrtool* (Strimmer, 2008) or *ConReg-R* (Li *et al.*, 2011). Careful consideration of all aspects of FDR estimation lead to discovering the impact of mutation in PRPF8 on mRNA splicing in retinal tissue (Korir *et al.*, 2014).

Analysis for Module Identification

A Gene's function is dependent on how the other genes in the cell function. For example, transcription factors' expression affects the expression of their downstream genes, coordinated expression or repression of multiple genes is important to carry out functions such as DNA replication, proliferation and apoptosis. Such functional dependencies among genes need to be elicited in the biological conditions under investigation. Though biological systems are complex, they are amenable to systematic analysis to

Fig. 6 (A) Desired or theoretical distribution of p-value, and (B–D) are typical distributions encountered in practice which need to be appropriately analyzed to get improved estimates of false discovery rates. The grey horizontal line shows the proportion of null hypotheses in the data, π_0 . Reproduced from Li *et al.* (2011).

Fig. 7 Transcriptomic clustering procedure and an example of hierarchical clustering of expression data. Reproduced from Lawlor *et al.* (2012). And k-means based consensus clustering of ovarian cancer data for subtyping. Reproduced from Tothill *et al.* (2008).

elicit these functional dependencies by identifying gene sets or modules associated with biological conditions using ‘module analysis’ approaches: (1) Clustering, (2) biclustering, and (3) differential network analysis.

Clustering is an unsupervised analysis technique to discover hidden structure in the data such as, gene modules and heterogeneity among samples. Of the multitude of clustering techniques, hierarchical and K-means clustering are used extensively. The clustering analysis procedure for gene expression data and examples of clustering are shown in Fig. 7. The *multiClust* (Lawlor *et al.*, 2016) is an easy-to-use R-package to deal with all steps associated with clustering, including visualization. However, ‘cluster’ (Eisen *et al.*, 1998) software offers an easy to use graphical interface for clustering, though it doesn’t offer important options for a variety of steps in clustering such as feature selection and distance metrics. The package “Treeview” (Eisen *et al.*, 1998) offers an easy to use graphical interface for interactive visualization of clustering results.

To eliminate spurious and unstable clustering of genes and samples, consensus clustering (CC) (Korir *et al.*, 2014) is employed. The central idea of consensus clustering is that the genes/samples that cluster together consistently for multiple bootstrap runs are the robust clusters and the remaining are spurious.

Clustering and CC analysis of expression data was successfully applied to identify subtypes in cancer. Cancers are typically classified depending on their tissue of origin. However, several genomic studies are providing more detailed molecular characterizations of tumors, and thus bring about the possibility of a more accurate classification based on their molecular profiling (Perou *et al.*, 2000; Tothill *et al.*, 2008). The molecular profiles, in *The Cancer Genome Atlas (TCGA)* project, revealed that cancer from the same tissue can be classified into molecular subtypes with distinct biology and clinical outcome. In many cases, molecular subtype information was shown to provide avenues for better therapeutic intervention.

Biclustering is based on mutually reinforcing modules of genes and samples, rather than all sample approach used in the clustering described above. The difference between biclustering and clustering (Chia and Karuturi, 2010) is depicted in Fig. 8. Biclustering was used to identify co-modules of genes and samples to elicit underlying biology in large cohorts of samples. *biclust* package (Kaiser and Leisch, 2008) allows researchers to explore a variety of biclustering algorithms which were shown to identify a different types of biclusters (Chia and Karuturi, 2010). The *ChiaKaruturi()* function in 'biclust' package can be used to unify the ranking of the biclusters output by multiple biclustering algorithms. Xie *et al.* (2018) provides overview of how biclustering was used in biological discovery.

Differential Network (co-expression) Analysis, in contrast to clustering and biclustering, is used to identify co-expressed gene modules in a supervised setting. In this case, we are interested in identifying gene modules that exhibit significant changes in their co-expression patterns, see Fig. 9 for illustration. It has been shown to be an effective technique to identify gene modules and hub genes in numerous studies (Bostrom *et al.*, 2011; Gillis and Pavlidis, 2009; Ray and Zhang, 2010). A variety of algorithms are available to conduct univariate (2-level or multi-level) and multivariate differential co-expression analysis (Kostka and Spang, 2004; Li and Karuturi, 2010; Karuturi *et al.*, 2006; Liany *et al.* 2017).

Variant Calling From RNA-seq Data

Identification of genomic variants (SNPs, Indels, SVs) is important to uncover the genotype and phenotype relationship. Whole exome sequencing (WES) and whole genome sequencing (WGS) are most commonly used to identify these genomic variants.

Fig. 8 Heatmaps (red for induction and green for repression) illustrating difference between clustering and biclustering (A) a cluster of genes, genes are co-expressed across all conditions; (B) a bicluster of genes, genes are co-expressed only among a subset of conditions (heatmap on the left) and the heatmap on the right shows no co-expression on the remaining conditions. Reproduced from Chia and Karuturi (2010).

Fig. 9 An illustration of differential co-expression, a gene module is co-expressed in normal samples but not in disease samples.

Recently, calling genomic variants from RNA-seq data has become popular as it offers the variant information for samples without WES/WGS data, and with corresponding WES/WGS data, it offers secondary validation for the variant calls from within expressed transcripts. Piskol *et al.* (2013) have shown that ~40%–50% of the coding variants identified in WGS data and 70% of the variants in expressed genes can be identified from RNA-seq.

The primary challenge in RNA-seq based variant calling is the accurate placement of reads in the genome. Additional complexity in the mapping arises due to RNA splicing. Average human exon length is 150 bp and common sequence reads are (2×100) which leads to the generation of reads crossing the splice junctions. This can create a significant problem in downstream variant calling due to misalignments and thus pipeline used for variant calling needs to have high-quality splice junction databases along with additional filters to remove the false calls. A procedure for variant calling, including the recommended filters, is given in the schematic in Fig. 10 (based on GATK best practices for RNA-seq variant calling and filter suggested in the Piskol *et al.* (2013)).

Analysis of Non-Coding RNAs (ncRNAs)

ncRNAs, such as miRNAs, exert their function by targeting mRNAs. Hence, it is important to understand the analysis of ncRNAs. We focus on the analysis of miRNAs and lncRNAs in this section. These procedures are used only when respective library preparation methods are used for sequencing.

miRNA-seq analysis

miRNAs belong to the family of small (~22 nucleotide long) ncRNAs and function as post-transcriptional regulators in plants and animals. miRNAs commonly function by binding to 3'UTR of target mRNAs and causing its cleavage or translation inhibition (Ambros, 2004; Lu *et al.*, 2008). Though, there is evidence that miRNAs may act as positive regulators in some cases (Vasudevan *et al.*, 2007). High conservation of miRNAs among evolutionarily divergent species suggests that these molecules are involved in essential biological processes (Pasquinelli *et al.*, 2000) such as cell growth, cell proliferations, embryonic development, apoptosis and tissue differentiation (Esquela-Kerscher and Slack, 2006).

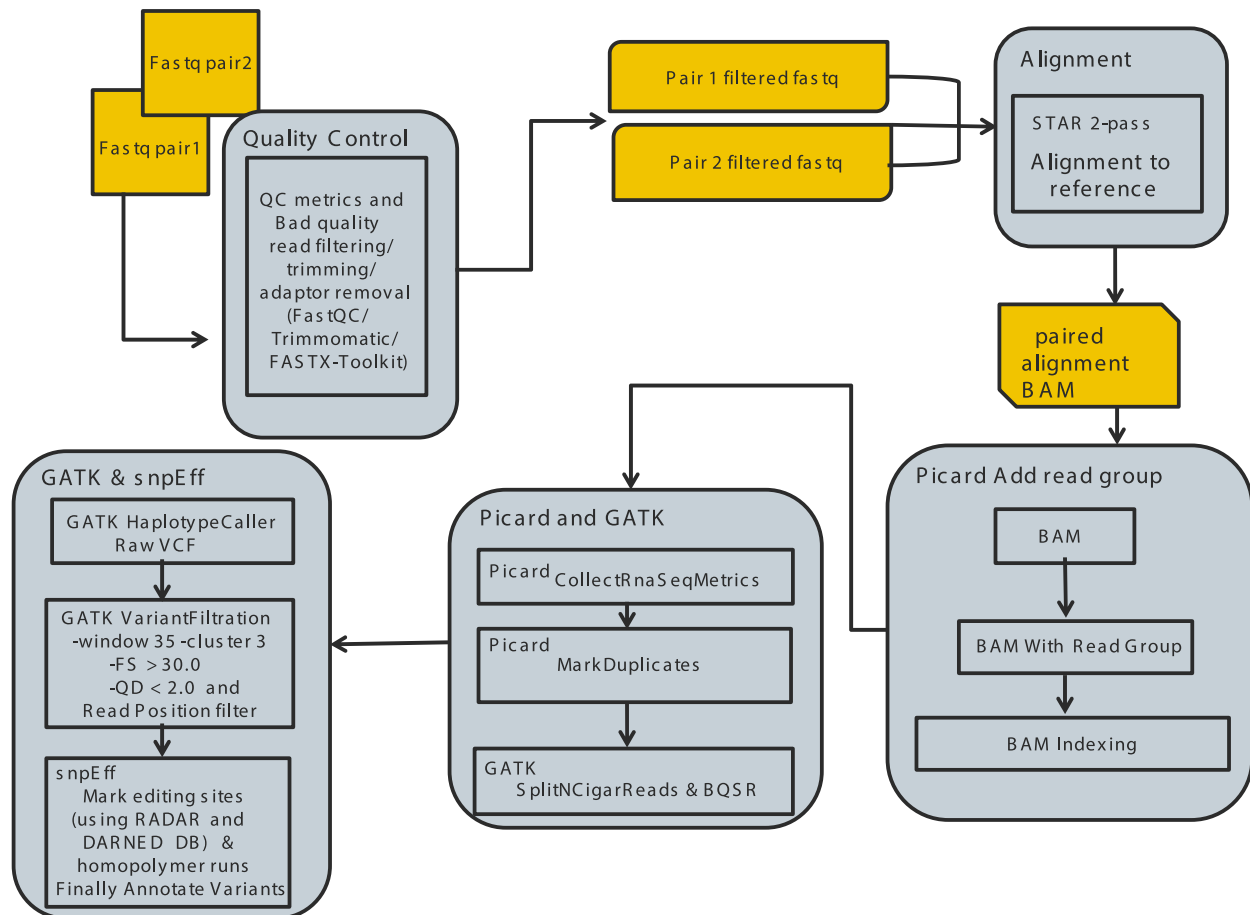

Fig. 10 Schematic of analysis of RNA-seq data for variant calling.

miRNA-seq data analysis scheme is shown in **Fig. 11(a)**. The first step in the analysis of miRNA-seq data is trimming of adaptor sequence and then examining the distribution of sequencing length to determine the quality of the library, peak at ~22 bp usually ensures high-quality library (**Fig. 11(b)**). Afterwards, depending on the goal of the experiment, sequences can be mapped to miRBase (a high-quality database of known miRNA species) or reference genome. Mapping to miRBase ([Kozomara and Griffiths-Jones, 2014](#)) will provide the quick estimation of the known miRNA species but mapping to the genome can detect novel miRNAs. Popular tools for miRNA analysis include miRdeep2 ([Friedlander et al., 2012](#)), miRanalyzer ([Hackenberg et al., 2011](#)) and miRspring ([Humphreys and Suter, 2013](#)). In [Pullagura et al. \(2018\)](#) we used these tools to investigate the requirement of the DICER cofactors TARBP2 and PRKRA in miRNA biogenesis.

lncRNA-seq analysis

Another class of ncRNAs is long ncRNAs (lncRNAs) with a length of more than 200 nucleotides ([Kung et al., 2013](#)). Numerous lncRNAs are present throughout the genome. One-way to classify them is according to their genomic location ([Kung et al., 2013](#)). According to the genomic location, lncRNAs can be classified as stand-alone lncRNAs (distinct transcription units located in sequence space not overlapping with protein-coding genes), Natural antisense transcripts, Pseudogenes ("remnant" of genes that have lost their coding potential due to mutations), Long intronic ncRNAs (Found within introns of annotated genes) and Divergent transcripts, promoter-associated transcripts, and enhancer RNAs (produced from the vicinity of transcription start sites or produced from the enhancer region). lncRNAs do perform various biological functions in a variety of developmental process and disease like cancer ([Huarte, 2015](#)). Typical bioinformatics workflow for the screening of lncRNAs has three steps: (i) Alignment to the genome of interest [Tophat2 and STAR]; (ii) reference guided (Cufflinks) or *ab initio* transcriptome assembly ([Guttman et al., 2010](#)); and, (iii) coding potential estimation of assembled transcripts ([Hu et al., 2017](#)). A comprehensive pipeline for lncRNA analysis is available online, see "Relevant Websites section".

Functional Analysis

The functional relevance analysis of the DEGs and gene modules is a critical step towards interpreting their function. It is typically carried out by conducting enrichment analysis of the pathways (e.g., KEGG ([Kanehisa et al., 2017](#))), Gene Ontology (GO) terms ([Ashburner et al., 2000](#)), and pre-identified publicly available gene signatures such as MSigDB ([Liberzon, 2014](#)), GeneSigDB ([Culhane et al., 2012](#)) and DSigDB ([Yoo et al., 2015](#)). The central idea is if a module represents a certain function, the genes in the relevant pathway or the signature will be enriched in the module. It is typically tested using Fisher's exact test ([Fisher, 1945](#)) or KS test as in GSA ([Subramanian et al., 2005](#)) and GSEA ([Subramanian et al., 2005](#)). However, GO-seq ([Young et al., 2010](#)) is recommended for the functional analysis of DEGs from RNA-seq data, GO-seq accounts for the gene length dependent bias in identifying DEGs (power to identify differential expression of longer genes is more in RNA-seq studies).

Diagnosis & prognosis

The National Institutes of Health Biomarkers Definitions Working Group defined a biomarker as a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a

(a) Schematic of miRNA-analysis

(b) Length based filtering of miRNAs from an RNA library

Fig. 11 Schematic of miRNA-seq data analysis procedure.

therapeutic intervention (Biomarkers Definitions Working, G, 2001). Gene expression signatures based biomarkers are used to diagnose disease (diagnostic biomarker) as well as to predict patient's prognosis (prognostic marker) or response to therapeutics (predictive marker) (Italiano, 2011).

In general, biomarkers are designed using systematic principles of classifier design. Based on the empirical study (Dudoit *et al.*, 2002) of gene expression based classifier design, simple classification algorithms like k-nearest neighbor (KNN) and diagonal linear discriminant analysis (DLDA) are recommended over more complicated classification algorithms like support vector machines (SVMs) for biomarker studies.

Single Cell Transcriptomic Analysis

Single cell transcriptome profiling is used to identify cell types, interactions among them and modeling stochasticity of gene expression in a sample, primarily using mRNA profiling. DEG analysis is fundamental to these objectives.

Differential Expression Analysis

The methods developed for identifying DEGs in bulk RNA-seq are suboptimal for scRNA-seq data due to higher noise contributed by both technical and biological factors specific to scRNA-seq data. The primary technical factors are low amount of transcriptome in a cell and hi-level of amplification required for sequencing which lead to amplification biases or dropout events i.e., the amplification or the capture is not successful for many mRNAs (Vallejos *et al.*, 2017). Biological variability is also higher in scRNA-seq data due to the stochastic nature of transcription (Raj *et al.*, 2006) and multimodality in gene expression (Shalek *et al.*, 2013) originating from the presence of multiple possible cell states within a cell population. All these together pose serious challenges for detection of DEGs.

Recently, several methods that explicitly model the technical and biological variability in scRNA-seq data have been developed to identify the DEGs in scRNA-seq data (Dal Molin *et al.*, 2017). Model-based Analysis of Single-cell Transcriptomics, MAST (Finak *et al.*, 2015), explicitly considers the dropouts using a bimodal distribution with expression strongly different from zero and proposes a generalized linear model to fit the data. Single-Cell Differential Expression (Kharchenko *et al.*, 2014), models the counts of each cell as a mixture of a zero-inflated Negative Binomial distribution and a dropout component and uses a Bayesian model to estimate the posterior probability that a gene is differentially expressed in one group with respect to another. Single-cell Differential Distributions, scDD (Korthauer *et al.*, 2016), is based on a multimodal Bayesian modeling framework for explicitly modeling the multimodal distributions of single cells and testing for differentially distributed genes associated with this multimodality.

Cell Type Identification

In a typical human body, there exists an estimated 40 trillion cells and is classified into approximately 200 cell-types based on morphology (Bianconi *et al.*, 2013). Advances in immunofluorescence and flow cytometry have enabled more refined classification based on the presence or absence of various surface markers (Pruszek *et al.*, 2007). However, the number of cell surface markers are limited to discern the plethora of cell types and these techniques are limited to easily dissociable tissues like blood (Roussel *et al.*, 2010). The development of scRNA-seq has changed the status quo and enabled the identification of novel cell-types based on the entire transcriptome of individual cells. scRNA-seq has been used to study different tissues and organs, both during development and at a fixed point in time (Rizvi *et al.*, 2017). Almost all the methods involve feature selection steps to remove noisy and irrelevant features, dimensionality reduction steps to avoid the "curse of dimensionality" and finally clustering steps to identify cell-types. The process of cell type identification and the recommended tools are outlined in Fig. 12. The most popular options currently available for each step are shown. These are not exhaustive lists and the most appropriate method in each step will depend on the data type and the technical platform used for generating the scRNA-seq data. SCEED package (Abrams *et al.*, 2018) helps in the experimental design and identifying optimal analysis procedure.

Cell:Cell Communication Analysis

Cell:Cell communication analysis is used to elicit cell communication networks facilitated by ligand-receptor interaction. *Single Cell-2-Cell Communicator* (SC2CC) [manuscript in preparation] helps identify cell:cell communication network using scRNA-seq data, in contrast to CCCExplorer (Choi *et al.*, 2015) which is used for sorted bulk RNA-seq data analysis. A preliminary version of SC2CC was used in Lawlor *et al.* (2017); Fig. 13. The primary features of SC2CC are: (1) SC2CC integrates cell type identification methodology described above into cell:cell communication analysis. (2) Selection of expressed ligands is based on both expression level and differential expression analysis. As scRNA-seq data enables identification of multiple cell types, SC2CC will identify differentially expressed ligands using multi-group analysis in *edgeR* and annotate a cell type with a ligand if the ligand's average expression in the cell type is more than the average expression in all cell types and it is significant by *edgeR* multi-group analysis. (3) SC2CC analyzes for both autocrine (cell communicates with itself) and paracrine (one cell communicates with another cell) signaling among all cell types. (4) SC2CC has augmented ligand-receptor pairs (1578, with 469 ligands and 342 receptors) database for the analysis. SC2CC identifies the receptor activation and assigns

Fig. 12 Steps involved in cell-type identification from single-cell RNA-seq data.

Fig. 13 Schematic of SC2CC.

autocrine/paracrine signaling using PAGODA (Fan *et al.*, 2016). The analysis of scRNA-seq data for cell:cell communication with SC2CC leads to a network of communication among different cell types, both autocrine and paracrine signaling.

Discussion

Transcriptomics data is a closer representation of abundance of regulatory molecules in the cell. In addition, the availability of easier-to-work and cost-effective technologies to generate transcriptomic data made it an integral part of most genomic studies, including disease genomics. Though mRNA, miRNA, and lncRNA are most commonly explored transcriptomic data, several other types of ncRNAs are being studied recently: circRNAs, piRNAs, and nasRNAs (Dong *et al.*, 2017; Kim *et al.*, 2009; Korneev and O'Shea, 2005; Weick and Miska, 2014). RNA specific library preparation methods have been employed to generate data for the type of RNA in consideration. Hence, several data processing steps need to be customized for the type of RNA analyzed. Multiple studies such as spermatogenesis require complex data processing of deeply sequenced data to effectively identify one type of ncRNA from the other type of ncRNAs (e.g., piRNAs from miRNAs) as they are of similar length and abundance. In addition to ncRNAs, fusion genes are another class of RNAs resulting from structural variations in the genome, especially in cancer transcriptomes. Several algorithms are available in the literature to identify fusion genes from RNA-seq data (Jia *et al.*, 2013; Kim and Salzberg, 2011). These methods analyze the junction reads (reads mapping to exons of different genes) and paired-end read mapping information (reads of the same paired-end read mapping to different genes). In addition, isoforms play a critical role in several biological systems, especially in the immune system. Though shotgun sequencing data (e.g., Illumina) has been used to identify isoforms, for better accuracy, it is being used in conjunction with long read sequencing technologies (PacBio and Oxford-nanopore) recently. These require specialized data processing steps (Weirather *et al.*, 2017).

Besides processing and analysis of primary RNA-seq data, a typical genomic study may require probing of transcriptomic data in different systems: model organisms, diseases, and populations. A variety of databases host plethora of transcriptomic data from a vast range of systems for researchers to query and examine the observations of the study in the context. Generic databases such as GEO and SRA, as well as specialized databases such as Oncomine (Rhodes *et al.*, 2004), CBio Portal (Cerami *et al.*, 2012; Gao *et al.*, 2013), and ImmGen (Heng *et al.*, 2008) facilitate such a contextual analysis and validation of the observations of the study. One of the major impediment to such a contextual analysis is the integration of data from multiple platforms as the transcriptomics data has been historically generated using a variety of platforms (e.g., microarrays: Affymetrix, Illumina, and Agilent; sequencing:

Illumina and PacBio, etc). Such an integrative analysis has to be carried out by considering platform specific normalization, and simple procedures such as z-scoring and housekeeping genes' based normalization have been proven to be useful.

In addition, most genomic studies include more than one type of transcriptomic data and genomic data (e.g., genomic variants data, epigenetic data, methylation data and TF-DNA interaction data). Typically, we are interested in studying the relationship and impact of a variety of genomic variants on the transcriptome. Each such analysis requires specialized integration strategies. For example, considerations of mapping single nucleotide or epigenetic variants in promoters to genes vary from that of enhancers or insulators due to their distance from genes; short-range structural variants may need to be interpreted differently from that of long-range structural variants. The strategies include mapping to the closest genes and conducting functional analysis of the mapped genes while accounting for non-uniform distribution of genes in the genome (McLean *et al.*, 2010; Zhou and Murthy Karuturi, 2012)

Taken together, transcriptomic data generation has been extremely impactful and the analysis is reasonably matured: from data processing, quality control, down-stream analysis and integrative analysis. Suitable experimental design, normalization and careful use of the plethora of databases will help elicit important biology of development and disease.

Author Contributions

George and Karuturi conceptualized and lead the writing of the chapter. All authors contributed equally to the chapter.

Regulation of Gene Expression

Y-h Taguchi, Chuo University, Tokyo, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

The Importance of Regulation of Gene Expression

The regulation of gene expression (Fig. 1) is critical process because of the following reasons. All multicellular organisms start their development from the duplication of a single cell: a fertilized egg. Then cascade of duplication results in the formation of multicellular organism. Since no cells' fate (i.e., into which tissues or organs each cell will differentiate) can be predicted, each cell must keep all set of genes everytime it is duplicated. Consequently, all of differentiated cells must keep full set of genes. Thus, it is critically important for each cell to control which genes should be expressed. Loss of proper controls might result in diseases, not functional organs, and even death.

Because of its importance, bioinformatics is also aiming to target regulation of gene expression. Although gene expression is composed of two steps: transcription and translation, both of which are samely important, because of imbalanced development of measurement technology, regulation of transcription is more extensively investigated than that of translation. Although translation is also an important process, because of inferior measurement technology, bioinformatics of translation process is investigated much less. Therefore this article also mainly describes regulation of transcription processes.

Pre-Transcriptional Regulation

Regulation of transcription process is divided to two parts, pre- and post-transcription regulation, respectively. Among these two, the pre-transcription regulation is more popular topics.

Transcription Factor Binding Site

Especially, inference of transcription factor binding site (TFBS) is ever attracting researchers' interest. TF is the protein that binds to promoter region and initiates transcription. Because of its sequence specific nature of binding, TFBS is a easy target to attack using bioinformatics that has great benefits of sequence analysis. Suppose that you have a set of DNA sequences identified by using some technology to which a TF often binds (e.g., ChIP-Seq). Then, all you need to do is to identify enriched sequence (so called motif) among those collection of DNA fragments. If you are very successful, you can predict where each TF binds along DNA sequence by searching where the identified motifs are located.

Promoter Methylation

Although TFBS has ever been studied since TF is protein which can be studied even in pre-genomic era, recent popular topics are not always directly related to protein; it is called epigenetics which means gene expression alteration without DNA sequence

Fig. 1 Schematic that outlines regulation of gene expression. TF bindings, promoter/DNA methylation, histone modification, and chromatin structure affect regulation of gene expression during pre-transcriptional phase. On the other hand, various non-coding RNAs (miRNA, lncRNA and circRNA) and RNA editing affect it during post-transcription phases. Although there are numerous additional protein machineries that mediate these processes, all of them are omitted in order for simplicity. Although non-coding RNAs also must be transcribed from DNA, this process was also excluded from this illustration in order to avoid complicatedness.

modification. Epigenetics is composed of multiple functional elements. Most extensively studied epigenetic effect is promoter methylation. If promoter is methylated, since the binding of TF to the promoter is disturbed, transcription of corresponding mRNA is also disturbed. Since exhausted measurements of promoter methylation was ever established and its functional importance is cleared out, promoter methylation was the most frequently measured epigenetics.

From the technical point of views, methylation is measured by bisulfite treatment that transforms unmethylated cytosine to uracil while methylated cytosine is not. Thus, comparison between original DNA sequence and that treated by bisulfite can give us the information about which cytosine is methylated.

Histone Modification

The next popular epigenetic measurements is histone modification (Senda and Adachi, 2013). Histone is a protein around which DNA winds. Correct and tight winding between DNA and histone is critically important to store DNA which is extremely long polynucleotide into small space that cell nuclei occupies. From the point of views of regulation of gene expression, histone modification can contribute to store DNA in small space since histone modification can alter how tightly DNA winds around histone. When the density of histone along DNA is low, DNA sequence is bared and is easy to be transcribed. On the other hand, if DNA tightly winds around histone, it is not easy for DNA to be transcribed. Histone modification that means binding of small molecules to histone tails can alter affinity between DNA and histone, thus can affect the easiness of DNA to be transcribed. Fortunately, histone is protein, thus we can make use of the technology invented for the identification of TFBS. We can measure which histone modification is enriched in which place along DNA. In contrast to the methylation, histone modification has more than twenty variations dependent upon which small molecule binds and where in histone tail it binds to, some of which contribute to expression of genes while others of which interrupt the transcription. Thus, complicated competition between multiple histone modifications can contribute to regulation of gene expression in the multiple ways.

Chromatin Structure

The third popularly measured epigenetics is chromatin structure itself. Chromatin is a complex composed of DNA and histone. As mentioned in the above, although histone modification can alter chromatin structure, histone modification is not an only factor affecting chromatin structure. Thus, chromatin structure can be an independent factor that can affect regulation of gene expression. In contrast to the promoter methylation and histone modification, there are no de facto standard measurement methodology of chromatin structure. It is measured by wide range of technologies.

Post-Transcriptional Regulation

Although all of these above are pre-transcriptional regulation of gene expression, alternatively, some post-transcriptional regulation of gene expression is also often considered.

miRNA Regulation of Gene Expression

miRNA regulation of gene expression is ever the most popular mechanism of post-transcriptional regulation of gene expression. miRNA is non-coding RNA whose length is as long as about 22 nucleotide. Their seed region composed of eight nucleotide binds to complementary polynucleotide region within 3 prime untranslated region of mRNA with the help of protein machinery. miRNAs that bind to target mRNA either degradate mRNAs or interrupt translation of mRNAs. The number of miRNAs is as many as 2000 and their regulation of gene expression is highly context dependent. Thus, in spite of importance within the field of disease and developmental researches, their functionality is not yet fully understood. No effective measurements of miRNA regulation of gene expression are yet proposed. The inference of miRNA-mRNA interaction from bioinformatics is still under the development stage.

Others

Epitranscriptomics is another field of post-transcriptional regulation of gene expression and come to be collecting researchers' interest recently. Epitranscriptomics is mainly studying RNA editing that affects mRNA functions. Although it is obvious that epitranscriptomics plays critical roles in regulation of gene expression, the comprehensive investigations of these functions has just started (Xiong *et al.*, 2017). Epitranscriptomics is composed of many kinds of modification of RNA; some examples are N¹-methyladenosine (m¹A), pseudouridine (Ψ), 5-methylcytidine (m⁵C), and N⁶-methyladenosine (m⁶A). They affect RNA in the various ways, e.g., affecting RNA structure, reducing mRNA stability, enhancing mRNA translation, and so on. At the moment, it is difficult to infer using bioinformatics the effect of epitranscriptomics toward regulation of gene expression.

Long non-coding RNA (lncRNA) is also an important factor that can regulate gene expression. lncRNA is defined as non-coding RNA longer than 200 nucleotide. It is known to contribute to modification of chromatin structure (Bhmdorfer and Wierzbicki, 2015) or to function as miRNA sponge (Wang *et al.*, 2015a). At the moment, it is difficult to relate lncRNA to regulation of gene expression directly. Thus, investigation in bioinformatics along this line is also under the development stage.

Circular RNA (circRNA) (Szabo and Salzman, 2016) can also work as miRNA sponge (Wang *et al.*, 2015a). CircRNA is a different class of non-coding RNA which is expected to play critical roles in regulation of gene expression. Nevertheless, its functions remains not well known. As shown by name, circRNA forms circular structure that is distinct from other non-coding RNA. Although there are some proposed data bases (Chen *et al.*, 2016; Glažar *et al.*, 2014) for circRNA, main study of circRNA is at the moment still their identification. Although the investigation of their functions is waited, it is not yet fully understood.

RNA structure was also started to be considered as contributors to regulation of gene expression (Jacobs *et al.*, 2012). This means, even secondary and/or tertiary structures of mRNAs can contribute to gene expression in post-transcriptional manner. In the study of RNA structure, although theoretical inference of secondary structures of RNA has ever developed, the understanding of its relationship to biological function remains not well studied. The possible way by which RNA structure can contribute to post-transcriptional process is to affect splicing. Alternate splicing is important mechanism that generates multiple proteins (isoforms) based on a single DNA sequence. Since splicing is mediated by the interaction of proteins and mature mRNA, structure of mRNA can alter the binding affinity between proteins and mRNA and as a result affect the splicing. RNA structure can also affect translation since translation is also mediated by the binding between mRNA and proteins that perform translation.

As a consequence, we can have distribution along DNA of various factors that might affect regulation of gene expression in the phase of pre-transcription as well as various factors that might affect regulation of gene expression in the phase of post-transcription. The next task, which is also a main topics from the bioinformatics point of views, is how to relate these factors to regulation of gene expression.

Identification of Relationship Between Various Factors and Regulation of Gene Expression

In order to interpret the various factors that might affect regulation of gene expression, we need to relate various factors to gene body. The most frequently employed, but not biologically validated, way is to use transcription start site (TSS). If some factors enriched around TSS, these factors are assumed to regulate expression of the corresponding genes. Typically, 500 bp upstream and 2000 bp downstream around TSS is used, but this range can be altered. Then, some factors enriched around TSS are assumed to regulate differentially gene expression.

Although it is one to one correspondence, more sophisticated ways are popular in now a day. For example, inference of gene regulatory network (Macneil and Walhout, 2011) (GRN) is a useful strategy. GRN is network representation of regulation of gene expression. Multiple factors are connected with multiple genes. This structure itself expresses the complex regulatory relation between gene expression and multiple factors. There are multiple ways to construct GRN from gene expression profiles, e.g., correlation based and Bayesian based. As for correlation based GRN, correlation between elements (e.g., mRNA and miRNA expression) were employed to evaluate if elements are related. Pairs of elements associated with the correlation coefficients (or their absolute values) larger than the threshold values (or associated with significantly small *P*-values) are connected in GRN and others are not connected. In Bayesian approach, Bayesian network having the maximum posterior probability (or likelihood) was sought. In addition to this, additional external information (e.g., protein-protein interaction or miRNA-mRNA target information) are often considered. After that hub elements that have many connections with other elements are selected as critical elements that can play critical roles in regulation of gene expression.

Measurement Technologies

Microarray

Microarray is an old technology to measure mRNA expression. It is still used for the measurements of various factors that contribute to regulation of gene expression. Methylation arrays is also used for the measurement of DNA methylation. ChIP technology was originally invented for the usage together with microarray. It is yet used for histone modification and TFBS. miRNA and lncRNA expression is even measured using microarray specifically designed for the measurements of miRNA or lncRNA. The advantages of microarray technology is its easiness to use once they are suitably designed. On the other hand, the weakness of this technology is that it is not usable for organisms other than model organisms, e.g. mouse and fly, that are often used for genomic study.

Short Read

High-throughput sequencing (HTS) is a newly invented technology alternative to microarray. Although it is still relatively more expensive than microarray, it has several advantages even for the measurements of factors that affect regulation of gene expression. For example, HTS can be applied to non-model organism while microarray is restricted to model organism to which microarray has already been designed as mentioned above. Although RNA must be converted to DNA before HTS, since HTS can directly count the number of DNA/RNA fragments, HTS is believed to be also more quantitative than microarray. If HTS is binded to ChIP technology invented for ChIP-chip technology for microarray, ChIP-seq technology can be used for the measure histone modification and TFBS. If HTS is combined with bisulfite treatments, HTS can also be used for identification DNA methylation. The

disadvantage of short read technology is that short read must be mapped to genome that is not always available. If genome sequence is missing, genome must be assembled independently prior to mapping short reads.

Long Read

Long read, which was invented by companies like nanopore (see Relevant Websites Section) or PacBio (see Relevant Websites Section), is the next generation HTS. In contrast to short read technology whose length is limited to up to a few hundreds nucleotide, long read technology can measure read as long as a few thousand nucleotides. At the moment, although long read technology is rarely used for studying regulation of gene expression, it has potential to open a new era for the research of regulation of gene expression. For example, long read has a potential to identify multiple factors binding to DNA illustrated in [Fig. 1](#) simultaneously. This might enable us to study interplay between these factors more accurately. Alternatively, long read technology can detect isoforms ([Byrne et al., 2017](#)) that short read technology can hardly identify since short fragments generated from distinct isoforms are hardly distinguished by short read technology. Since there is a possibility that distinct isoforms are differently regulated by various factors, employment of long read technology might be critical in order to understand regulation of gene expression more precisely.

Applications

There are some applications aiming these above purposes. Especially, Bioconductor ([Huber et al., 2015](#)) platform provides many ready made and useful packages.

GRN

For example, GeneNetworkBuilder ([Ou et al., 2017](#)) package generates GRN from ChIP-chip/ChIP-seq and expression data. If your data set is time course, GRENITS ([Morrissey, 2012](#)) can be used. CoRegNet ([Nicolle et al., 2015](#)) is another package that infers GRN from gene expression, TFBS and ChIP data set.

TFBS/Histone Modification

TFBSTools ([Tan and Lenhard, 2016](#)) is well made package that can analyze data for the identification of TFBS. Ringo ([Toedling et al., 2007](#)) aims investigation of ChIP-chip microarray. BAC ([Gottardo, 2007](#)) uses a Bayesian hierarchical model to detect enriched regions from ChIP-chip experiments. Starr ([Zacher et al., 2009](#)) aims simple tiling array analysis of Affymetrix ChIP-chip data. Rcade ([Cairns, 2017](#)) aims analysis of ChIP-seq and differential expression. geneXtender ([Khomtchouk et al., 2017](#)) is designed to process histone Modification ChIP-seq data. rMAT ([Cheung et al., 2017](#)) is implementation from MAT program to normalize and analyze tiling arrays and ChIP-chip data. iChip ([Mo, 2012](#)) is Bayesian modeling of ChIP-chip data through hidden Ising models. Using these packages, researchers easily relate gene expression and TF binding and/or histone modifications

Chromatin State

There is a STAN ([Zacher et al., 2014](#)) that infers chromatin state from histone modification as well as DNA methylation. DChIPRep ([Chabbert et al., 2016](#)) also infers chromatin structure from ChIP-seq data set.

DNA Methylation

As for DNA methylation, ChAMP ([Tian et al., 2017](#)) provides us the method of processing methylation array. BPRMeth ([Kapourani, 2017](#)) is another package that can extract methylation profiles from HTS gene expression and row methylation profiles.

RNA Structure

RNAprobR ([Kielpinski et al., 2015](#)) is a package that processes HTS data for the identification of RNA structure.

Gene Expression

In order to investigate regulation of gene expression, it is of course necessary to predict gene expression itself. However, it should have been discussed in other topics. Thus, this is not discussed here. Access other topics.

miRNA and lncRNA

Expression profiles of miRNA and lncRNA are easily obtained by HTS and microarray. Although treatment of miRNA/lncRNA array is similar to that of mRNA arrays, miRNA-seq does differ from RNA-seq aiming to measure mRNA expression (lncRNA-seq can be

treated similarly to RNA-seq). The researcher must use tools designed specifically for miRNA profile. As for miRNA-seq, miRDeep2 (Friedlander *et al.*, 2011) or miRDeep* (An *et al.*, 2012) are popular tools. Unfortunately, there are no de facto standard methods that relate miRNA expression to mRNA expression, although some tools are available (Wang *et al.*, 2015b) in Bioconductor. First of all, we need to know which mRNAs individual miRNAs target. Nevertheless, mRNA-miRNA interaction is highly context dependent. Even the most trustable experimentally validated miRNA-mRNA interaction database, miRTarBase (Chou *et al.*, 2015), is only valid for the diseases form which experimental results were collected. Thus, at the moment, although miRNA is believed to play critical roles in regulation of gene expression, it is practically difficult to relate miRNA expression to mRNA expression.

Illustrative Examples

In order to make easier to understand how one can process data sets, some illustrative examples are presented in the below. Since most of packages included in Bioconductor are accompanied with more examples, see documents attached with these packages for more examples.

Methylation Analysis Using ChAMP

Suppose R (R Core Team, 2017) is installed. In order to run with sample data sets, try Fig. 2 in R. Then the list of genes associated with differential methylation regions should be in my DMR. In order to list genes, try Fig. 3. You can get a list of chromosomal regions, associated *P*-values, and genes having overlapping promoters. The sample data set is 450 k lung tumor data set and contains only 8 samples, 4 lung tumor samples and 4 control samples.

State Identification Using STAN

STAN enables us to identify chromosomal state with considering histone modification as well as methylation profiles. In order to run with sample data sets, try Fig. 4 in R. In order to see results try Fig. 5. Now, chromosomal regions are classified into ten classes with considering histone modification as well as methylation profiles. The sample data set contains ChIP-Seq experiments of seven histone modifications (H3K4me1, H3K4me3, H3K36me3, H3K27me3, H3K27ac and H3K9ac), as well as DNase-Seq and genomic input.

Discussion

In the above, multiple factors that contribute to regulation of gene expression, technologies that measure these factors and bioinformatics tools to analyze these factors were discussed. Investigation of these factors are still on going and additional new factors that contribute to regulation of gene expression might appear. As more data accumulate and more technology develop, the manner of relating these factors to regulation of gene expression will become more complicated. Thus, the researchers aiming analysis of regulation of gene expression need to try to continuously collect updated knowledge. Even when simply more data become available, the conventional views listed in the above might be altered. The study of regulation of gene expression is on going and just started field. If there would be the revised version of this topics in the future, contents will be altered drastically.

Future Direction

Future direction of this topics is definitely the integration of multiple omics data set, i.e., trans omics analysis (Yugi *et al.*, 2016). As can be seen in the above multiple factors contribute to regulation of gene expression with interacting with one another. In spite of that, most of researches currently performed is mainly on regulation of gene expression with considering individual factors.

In spite of serious need along this direction, no established methods on trans omics analysis exist. Some promising direction includes network based (Yugi *et al.*, 2016), gene set enrichment analysis based (Zhang *et al.*, 2015), and tensor based (Taguchi, 2017) ones. Nevertheless, the best-fitted method for trans omics analysis is still continuously sought.

Concluding Remarks

In this article, various factors that might affect regulation of genes were discussed together with measurements technology and software that can process these measurements. Although it was not yet employed for the study of regulation of gene expression, single cell sequencing technology must be employed since regulation of gene expression differs from cell to cell. After the success of this direction, we might understand cellular function that manages regulation of gene expression more precisely.

Biographical Sketch

Prof. Y-h. Taguchi is a physics professor at Department of Physics, Chuo University, Tokyo, Japan. He has obtained Dr. Sci. at 1988 for Statistical Physics, from Tokyo Institute of Technology, Japan. He has been an assistant Professor at Department of Physics, Tokyo Institute of Technology, 1988. Then, he has move to the present position as an associate professor at 1997. He has been a full professor since 2006. He has published more than 90 peer reviewed and conference proceedings papers including 28 single authored papers. His main present interests are feature extraction and feature selection using principal component analysis and tensor decomposition. His methods were applied to transcriptome and epigenetic profiles, which were further applied to in silico drug discovery as well as biomarker identification.

Comparative Transcriptomics Analysis

Y-h Taguchi, Chuo University, Tokyo, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

Comparative Transcriptomics Analysis (CTA) is, as the name implies, the comparisons of the amount of transcripts between two distinct conditions. Typical distinct conditions are healthy controls vs disease patients, a pair of distinct tissues, distinct time points and even distinct species. The reason for this frequent execution of CTA is because almost all cells keep the full set of genes, although not all of the genes are expressed. Because of this sharing of the full set of genes between cells, CTA is a primary method to investigate the factors that make cells distinct from one another.

In contrast to the clearer purpose of CTA, performing CTA is much harder. This is primarily because the amount of transcripts is naturally a real number. Since real numbers cannot be exactly equal to one another by chance, we need some criterion when the amounts of two transcripts can be regarded to differ from each other. The most simplest solution of this problem is the introduction of some statistical models. Based upon the statistical models under the null hypothesis that the amounts of two transcripts are equal, we can identify transcripts associated with distinct values between two conditions by rejecting the null hypothesis. Thus, the point is how to assume the null hypothesis with which statistical models are assumed.

Dependent upon assumed statistical models, various strategies of CTA are possible. They are primarily divided to two categories dependent upon what kind of technology is used to measure the amount of transcript. The major two such technologies are microarray and high throughput sequencing (HTS), respectively. Although these two technologies measure biologically the same variables, i.e., the amount of transcripts, the outcomes differ from each other. In microarray, the amounts of transcripts measured are inevitably real numbers, since microarray measures the amount of transcripts by the amount of light emission from nucleotide fragments that bind to complementary probes. On the other hands, the amount of transcript measured by HTS must be integer, since HTS counts the number of fragments cut out from mRNA. Since suitable statistical models for real numbers and integer differ, in the following, I separately discuss the basics and the applications of the two.

Statistical Models

Microarray

As described in the above, statistical models applied to the amount of transcripts measured by microarray must be that of real numbers. Most of popular statistical models assume that the amount of the transcript obeys t distribution, $t(n)$, where n is the number of samples in each class. When aiming to identify genes that have distinct mean μ between two classes, the null hypothesis that μ is equivalent between two classes is rejected with some P -value that is the threshold value, e.g., 0.05.

t -test is only applicable to two classes problem. Although t -test can be formally applied to multiple classes by dividing multiple classes to a set of pairwise comparison, it is erroneous because of the following reason. Suppose we have K multiple classes. Then, the number of pairwise comparisons is as many as $K(K-1)/2$. Thus, $P=2/K(K-1)$ can be achieved by chance. If K is as large as ten, since $P=2/K(K-1) \simeq 0.02$, usual threshold value $P=0.05$ is clearly meaningless. If P -values are corrected, e.g., $P<0.05 \times 2/K(K-1)$, the ability that t -test can detect genes associated with distinct amount of transcript between any pairs of multiple classes will drastically decrease.

In order to avoid these problems, for the CTAs associated with multiple classes, other strategies are employed. These other strategies include categorical regression (in other words, analysis of variance (ANOVA) (Upton and Cook, 2008)), χ^2 test, or any other extensions of them. Details of implementations differ from applications to applications, it will be discussed in the below in the applications section.

HTS

HTS is an alternate technology that can outperform microarray that has many limitations. Microarray must be designed prior to measurements. This means, non-model organisms are hard to be tested. In HTS, we do not need anything prior to the measurements, although genome sequence must be decided if it is not available prior to counting of the number of reads attributed to each gene. Genome sequence also can be decided by HTS.

HTS is roughly divided to two classes: genome sequencing and RNA-seq. In genome sequencing, fragmented genomic DNA are sequenced and whole genome is assembled from the reads sequence. On the other hand, RNA-seq tries to sequence reads taken from RNAs. For both cases, read can be single end or paired ends. For the latter, reads are generated from both ends of longer fragmented DNA or RNA. This strategy can increase the accuracy than the single end, because paired ends require additional constraint that paired end must be within the length of mRNA and fragmented DNA.

Assembling fragmented DNA to get whole genome sequence and transforming RNA-seq reads into transcript with consideration of splicing are the issues of statistical modeling. In other words, they are the tasks that decide the most probable genome sequence or mapping of RNA-seq reads to genome, based on the obtained read sequences. Since the measurement of the amount of transcript itself is out of scope of this article, refer to other articles for more details.

In contrast to the conventional HTS, where length of read sequences is limited to up to a few hundreds nucleotide, an alternative technology, long read sequencing (e.g., nanopore and PacBio, see Relevant Websites section), is recently gaining traction. In long read technology, each read can be as long as a few thousand nucleotides, which is long enough to measure whole genome of prokaryotes and individual whole transcript of eukaryotes. This has several advantages compared with short read technologies. For prokaryotes genome, it is obvious that long read technology allows to omit assembly in order to obtain whole genome sequences. For eukaryote transcripts, complicated splice junction identification process can be omitted. Thus, short read technology soon will be completely replaced with long read technologies.

Normalization

Prior to CTA, the amount of transcript must be normalized, since independent of the measurement technologies, microarray or HTS, the total amount of transcript is impossible to control during measurement. This process can be done either outside of CTA or as a part of CTA. In the former case, researchers can select their favorable methods while the latter employs the pre-defined strategy for normalization. In any case, dependent on the normalization strategy, the outcome of CTA varies and there are no de facto standard techniques for the normalization prior to CTA. This is an additional reason why CTA is difficult to perform, since incorrect normalization might result in the miss-identification of genes expressed distinctly between two conditions. Various applications aiming normalization prior to CTA will be introduced in applications section below.

Fold Change

Even if some genes can be identified as expressed differently between two conditions based on the criterion given by a statistical test, some genes might likely not biologically play critical roles. This is because the standard statistical tests often ignore the amount of transcripts itself. For example, in *t*-test, very small difference of μ s between two classes can be judged as significant when estimated standard deviation in each class is much smaller than the estimated difference of μ s between two classes. In extreme case, when the amounts of transcript in each class are completely same within each class, i.e., standard deviation is equal to zero, any tiny difference of μ s between two classes can be regarded as significant, since $P=0$. Nevertheless, such a judgement is clearly meaningless from the biological point of views (Conversely, genes not associated with significant difference may biologically function. This often simply means inability of tests because of, e.g., not enough number of available samples).

In order to avoid these somewhat meaningless identifications of genes associated with distinct amount of transcript between distinct classes, fold change is often considered together with statistical tests. Fold change is often useful to screen genes associated with differential expression when statistical test cannot list any genes with significantly smaller *P*-values. Fold change is, as its name says, the ratio between the amount of transcripts in two classes. Then, genes associated with both significantly small *P*-values and large enough fold change (e.g., larger than two or less than a half) are regarded to be those associated with significant difference of amount of transcript between two classes. Although this strategy is known to work well empirically, there are no systematic ways that can decide how large or small fold change (larger than twice, larger than three times, smaller than one half, or smaller than one third) should be employed in order to get biologically reasonable answers.

Multiple Comparisons

Multiple comparison is another issue of CTA. Any statistical test can attribute to each gene, *P*-values that reject null hypothesis that two classes are equivalent in some sense. Nevertheless, since the number of genes is huge (c.a. 10^4), these *P*-values are misleading. If the number of genes is *N*, $P=1/N$ can happen by chance. This suggests that the frequently used criterion that $P<0.05$ is significant is useless.

At the moment, although there are no definite ways to address this problem, numerous trials were proposed. The simplest one is Bonferroni (Armstrong, 2014) where *P* is transformed to be *NP*. This apparently simple transformation has drawback that often misses the significant difference because of its too strict criterion. More robust way is to assume the uniform distribution for *P*-values. If null hypothesis is true, *P*-values must obey uniform distribution. Then, genes whose attributed *P*-values deviate from uniform distribution is regarded to be significant. The most frequently used criterion along this line is Benjamin-Hochberg (Benjamini and Hochberg, 1995). Empirically, the latter strategy was more often employed, since it can give us more biologically reasonable (interpretable) results empirically.

Batch Effect

Although it is somewhat related to normalization issue, batch effect can often heavily affect the outcomes of CTA. Batch effects generally means the uncontrollable external factors that can affect measured amount of transcript. Numerous factors can cause batch effects, e.g.,

days, time, institutes, persons, and so on. If batch effect is not removed effectively, CTA results in not the comparison between treated and control samples, but that among batches. Although there are many packages proposed for removing batch effects (Reese *et al.*, 2013; Leek, 2014; Chen *et al.*, 2011), there are no de facto standard methods that can remove batch effect well independent of the experimental situations. The best strategy that researchers can employ is to evaluate outcomes with considering biological significance of outcomes carefully. In principal, it is dangerous to mix gene expression profiles taken from different batches.

Enrichment Analysis

Although it is not directly related to CTA, biological interpretation of selected genes is often required and important. One of typical analysis for this purpose is enrichment analysis. In enrichment analysis, a set of genes is given, and various biological terms associated with the gene set with significantly small *P*-values computed by some statistical test, e.g., Fisher's exact test, are identified.

Here I list some of famous servers to be used for this purpose: DAVID (Huang *et al.*, 2008), g:profiler (Reimand *et al.*, 2016), TargetMine (Chen *et al.*, 2016), Enricher (Kuleshov *et al.*, 2016), IPA (QIAGEN, 2017) and MSigDB (Subramanian *et al.*, 2005), although they have their own pros and cons.

qPCR

Other than two major technologies, microarray and HTS, quantitative polymerase chain reaction (qPCR) is also sometimes used to measure amount of transcript. In spite of the quantitative accuracy of qPCR compared with other two technologies, qPCR is used only less frequently. This is because qPCR has no ability to measure numerous transcripts simultaneously. For each transcript, experiments must be repeated independently. This is far from cost effective. In addition to this, qPCR often requires reference transcript that is not altered between treated and control samples. Since either identification of not altered transcript or artificial spike in of reference genes are additional time and cost consuming process, qPCR is mainly used for validating the limited number of transcripts among all transcripts measured by either microarray or HTS.

Single Cell Analysis

Although single cell analysis (SCA) (Yuan *et al.*, 2017), which measures transcripts cell by cell, is a rising field, it is not developed enough to be included in this encyclopedia as an established field. First of all, because of technology currently developing, some transcripts are often missing. At the moment, there are no ways to judge if missing transcript is really missing (biologically) or not (technologically missing, i.e., failure of measurements). Thus, the purpose of SCA is often presently not identifying genes whose transcripts are expressed distinctly between treated and control samples, but clustering (grouping) cells based upon the measured transcripts. Since clustering cells is somewhat outside of CTA, SCA is not discussed here in details. Nonetheless, SCA is surely replacing conventional CTA in the future when the SCA technology is established.

Applications

There are numerous applications for CTA. In this article, those in Bioconductor (Huber *et al.*, 2015) will be specifically introduced.

Normalization for Microarray

There are numerous methods to achieve normalization prior to CTA for microarray. There are generally two branches along this direction. The first one is the normalization based upon single microarray. This means that the amount of transcript is normalized with considering single measurement. One of the most frequent methodologies of single array based normalization is mas5, which is implemented as mas5 function, included in affy (Gautier *et al.*, 2004) package. In single microarray based normalization, total amount of transcripts is assumed to be constant, independent of measurements. Another frequent strategy is normalization based upon multiple array. The most popular one along this direction is rma, which is implemented as rma function, also included in affy (Gautier *et al.*, 2004) package. In multiple array based strategy, the amount of transcripts that share ranking among multiple arrays are assumed to take the same values. In actual, there are no ways by which we can judge the better one between these two. Generally speaking, multiple array based strategies are more popular since they are less affected by individual measurements. In principle, the choice of better strategy is highly context dependent. It must be evaluated based upon the biological outcomes.

Normalization for HTS

Although the amount of transcripts obtained by HTS technology is an integer, it has different difficulties than microarray normalization. Since the number of reads are that of RNA fragments, the number of reads mapped to individual genes is not proportional to the amount of transcripts. It is obvious that longer RNA has more fragments. This is a sharp contrast to microarray

where the amount of transcripts measured is per gene base. Thus, there are two kinds of normalization strategy. One is to transform the number of reads mapped to each gene to that of per gene base. The most frequent definition of this line is RPKM (Reads per million mapped reads), which is defined as

$$\text{raw counts} \times \frac{10^6}{\text{all reads}} \times \frac{10^3}{\text{gene length}}$$

where raw counts is the number of reads mapped to each gene, all reads are total number of reads in each measurement. Although it looks reasonable, there is one drawback. When single gene expression drastically increases, because of all reads in denominator, all of other transcripts are regarded as being decreased, although it is clearly not reasonable.

Another strategy is raw reads, which is without any normalization. It might look strange, but raw reads as it is can be treated if suitable statistical models are proposed (see below).

CTA for Real Numbers

Since RPKM is a real number analogous to the amount of transcripts measured by microarray, we discuss these with that of microarray. As for CTA of real numbers, there are huge number of applications. Here I introduce two of them as the most frequently used ones. The first one is SAM (Significance Analysis of Microarrays) (Tusher *et al.*, 2001), which is implemented as sam function in siggenes package (Schwender, 2012). It can deal with both two classes and multiple classes, by employing modified *t*-test and χ^2 test accordingly. Another one is limma (Ritchie *et al.*, 2015), which is based upon linear model assuming Bayesian work frame. limma can also deal with both two classes and multiple classes. In actual, limma can be adapted to almost all situations, since it employs design matrix strategy by which user can designate any kinds of possible comparisons. sam and limma also can give users the adjusted *P*-values which considered multiple comparison criterion. Thus, researchers do not have to consider correction assuming multiple comparisons.

CTA for Integer Numbers

Since reads count by HTS is positive integers, we need null hypothesis fitted to this situation. Although Poisson distribution has long been employed, it has one “drawback”; since Poisson distribution has only one parameter, it cannot be fitted to mean and variance simultaneously. In order to overcome this problem, negative binomial distribution is more often used. DESeq2 (Love *et al.*, 2014) is the most frequently used packages for this purpose. It also accepts raw reads as input and normalization is included in the data processing. It also gives us adjusted *P*-values so as not to consider multiple comparisons separately. It is also fitted to both two classes and multiple classes, since it employ design matrix strategy that limma employs.

In spite of frequent and successful usage of DESeq2 in CTA of HTS, the appearance of negative binomial distribution is not always guaranteed, since it lacks convergence theorem that normal distribution has. Because of this drawback, a non-parametric strategy is sometimes employed. NOISeq (Tarazona *et al.*, 2015) is one of the most frequently used non-parametric packages. NOISeq also implements data normalization, multiple comparison corrections, adapted to both two classes and multiple classes and so on.

CTA often results in distinct outcomes between DESeq2 and NOISeq. As in the microarray, there are not definite criteria that decide the best applications.

Conclusions

In summary, CTA is rather art than science. At the moment, there are no definite ways guaranteed to always work well regardless the situations considered. CTA must be done with much care in order to avoid getting results without any biological meanings. It is not an easy way, but must be tried.

Analyzing Transcriptome-Phenotype Correlations

Bryan T Li and Jin X Lim, Temasek Polytechnic, Singapore

Maurice HT Ling, Colossus Technologies LLP, Singapore

© 2019 Elsevier Inc. All rights reserved.

Introduction: Network Effects Between Transcriptome and Phenotype

Consider an electronic musician facing potentially thousands of knobs, switches, and myriad of various controls on his digital instruments and software. Although each dial, such as volume control, can be adjusted by the composer independently but it may be connected to one or more dials. For example, an incremental unit on Dial A may result in 0.1 unit increment to the setting on Dial B and 0.15 unit decrement to the setting on Dial C. Dial B and C may in turn affect other dials, which may then indirectly affect Dial A. The task of the musician is to manipulate the various controls to compose a techno piece.

In this analogy, each control represents a gene and the setting on that control represents the transcription level of that gene. The diversity of controls represents the thousands of genes in the genome. Given that the genome of each cell is identical in an organism (which several exceptions, such as immunoglobulin-producing cells), the musician represents the external stimuli to the cell and the relationships between the controls represent the complex network of signalling cross-talk where the expression of one gene may up-regulate or down-regulate other genes to varying degrees. Hence, how can the same set of controls (genome) result in different musical pieces (phenotype)?

It has been known that changes in the transcriptome may result in phenotypic changes (Sul *et al.*, 2009), some of which may result in diseased conditions; such as oncogenesis (Kang *et al.*, 2009), metabolic effects (Kyung *et al.*, 2017), or other diseases (Casamassimi *et al.*, 2017). However, the determination of phenotype from transcriptome may not be direct and can be affected by multiple levels of modulations (Fig. 1). For example, the effective concentration of the mRNA transcript may be affected by its antisense transcript expression (Zhao *et al.*, 2014b) and half-life (Belgrader *et al.*, 1994), various sequence features on the mRNA transcript may affect transcription efficiency leading to varying protein levels given the same amount of mRNA transcript (Evfratov *et al.*, 2017; Gamble *et al.*, 2016; Hockenberry *et al.*, 2017; Kumar *et al.*, 2014; Lahtvee *et al.*, 2017), and the effective abundance of each protein may be affected by varying half-life (Fishbain *et al.*, 2015).

Although phenotype prediction may be best carried out from proteome, the experimental techniques for large-scale proteomics studies are less developed compared to transcriptomics or genomics studies. A reason is that most transcriptome and genome techniques are based on polymerase chain reaction, which only exist for nucleic acids, and corresponding technique is absent in proteomics studies. Hence, a large volume of transcriptomics studies and data is present. Thus, there are substantial benefits to be able to predict phenotype from its transcriptome.

Determining the Transcriptome

The transcriptome is defined as the complete set of transcripts in a cell, and their quantity, for a specific developmental stage or physiological condition (Wang *et al.*, 2009). Transcripts are RNAs, the single-stranded nucleic acids, which possesses structural and

Fig. 1 Levels of omics and molecules between transcriptome and phenotype.

regulatory roles in many cellular processes. It is classified as protein-coding RNAs and nonprotein-coding RNAs (Eddy, 2001). Methods to comprehensively and systematically interrogate the expression of virtually all these RNA species have been developed over the past 20 years, from the initial expression sequencing tag (EST) based method (Boguski *et al.*, 1994), to serial analysis of gene expression, SAGE (Velculescu *et al.*, 1995) and cap analysis gene expression, CAGE (Shiraki *et al.*, 2003), to the hybridization based gene microarray (Lashkari *et al.*, 1997; Schena *et al.*, 1995), and now the RNA-seq (Wang *et al.*, 2009). The use of next generation sequencing (NGS) technology allows for a higher throughput and resolution level of transcriptome studies (Mardis, 2008).

EST Based Method. An expression sequencing tag (EST) is a short sub-sequence of a cDNA sequence. ESTs can be rapidly generated from either the 5' or 3' end of a cDNA clone in a high-throughput manner. In 1992, scientists at NCBI developed a new database, called dbEST, designed to serve as a collection point for ESTs. Data are submitted directly by laboratories and are not curated. Private EST databases such as SANBI (South Africa), MIPS (Munich), TIGEM (Italy) and DOTS (Pennsylvania) exist. Since ESTs represent portions of expressed genes, Sanger sequencing of EST is used in the early days of genome research (Boguski *et al.*, 1994). ESTs can be used to design probes for DNA microarrays as well. However, it is impossible to achieve transcriptomic quantitative analysis using this method because of the limitation on throughput and high cost.

SAGE and CAGE. SAGE was invented by Dr. Victor Velculescu in 1995 to allow quantitative and simultaneous analysis of a large number of transcripts (Velculescu *et al.*, 1995). The mRNA of an input sample is isolated, and cDNA is synthesized by means of biotinylated oligonucleotide primer. The cDNA is immobilized to streptavidin beads and type II restriction enzyme such as *NlaIII* is used to cleave cDNA to an average length of 256 bp with sticky ends. Captured cDNAs are ligated to linkers and then cleaved using tagging enzyme such as *BsmF1*. The ends were repaired using DNA polymerase to produce blunt end cDNA fragments. T4 DNA ligase is used to link two tags to form a 'ditag' with linker on either end. These linker-ditag-linker constructs are amplified by PCR, digested by the original anchoring enzyme, and then link together with other ditags to form cDNA concatemers. These concatemers are inserted into bacteria to create more copies, sequenced using high-throughput DNA sequencers and analyzed with computer programs. Over the years, variants of SAGE; such as, LongSAGE (Saha *et al.*, 2002), RL-SAGE (Gowda *et al.*, 2004) and SuperSAGE (Matsumura *et al.*, 2005) have been developed.

While in SAGE, multiple 3' cDNA ends were concatenated to be one close, CAGE concatenated the 5' cDNA ends. The original CAGE method (Shiraki *et al.*, 2003) was using biotinylated cap-trapper for capturing the 5' ends, oligo-dT₁₂₋₁₈ primers with superscript II RT in the presence of trehalose and sorbitol for synthesizing the cDNAs, the class II restriction enzyme Mmel for cleaving the tags, and the Sanger method (Sanger and Coulson, 1975; Sanger *et al.*, 1977) for sequencing them. To better detect the non-polyadenylated RNAs, random reverse-transcription primers were introduced (Kodzius *et al.*, 2006).

The output of SAGE and CAGE are a set of short nucleotide sequences known as tags with their observed counts. Using a reference genome, the mRNA from which the tag was extracted and its abundance could be obtained. Although protocols like *nAnTi-CAGE* (Murata *et al.*, 2014) and updated *nanoCAGE* (Poulain *et al.*, 2017) are published recently, due to the high cost of Sanger method for sequencing and the difficulty to map tags to the genome, CAGE and SAGE were most replaced by DNA microarray.

Microarray. The Microarray is based on nucleic acid hybridization. An array is constructed by immobilizing oligonucleotide probes on a solid support such as a silicon chip in an orderly manner. In the late 90's, DNA array technology progressed rapidly and three basic types of arrays production methods emerged during this frame: spotted arrays on glass (DeRisi *et al.*, 1996), *in-situ* synthesized arrays (Fodor *et al.*, 1991) and self-assembled arrays (Ferguson *et al.*, 2000; Michael *et al.*, 1998; Steemers *et al.*, 2000; Walt, 2000). Fluorescence-labeled cDNA is incubated with the chip. Due to complementary binding of the cDNA to the probe, the abundance of cDNA, hence the RNA can be determined by measuring the fluorescence density. Several different types of microarrays; such as, splicing-specific microarray (Clark *et al.*, 2002) and genome tiling array (Bertone *et al.*, 2004); had been developed to cater for different needs.

The microarray is based on hybridization and can only detect sequences that the array was designed to detect. Genes that have not yet been annotated in a genome or non-coding RNAs that are not yet recognized as expressed cannot be detected and RNA molecules sharing high sequence similarity cannot be distinguished from one another using this method. The advent of next generation sequencing technologies combined with the rapid decrease in the cost of sequencing makes RNA-seq (Wang *et al.*, 2009) the method of choice for measuring transcriptomes (Ledford, 2008; Su *et al.*, 2014; Zhao *et al.*, 2014a).

RNA-seq. RNA-seq refers to the combination of high-throughput next generation sequencing (NGS) with computational method to capture and quantify transcripts present in an RNA extract (Ozsolak and Milos, 2011). The RNA transcripts are isolated and reversely transcribed into cDNA. Massive parallel signature sequencing (Brenner *et al.*, 2000), which consists of four rounds of restriction enzyme digestion and ligation reaction, is used to generate sequence tags of 25–500 bp. By analyzing these tags, the transcriptome can be studied qualitatively and quantitatively (Nagalakshmi *et al.*, 2008).

The NGS technique generates a large volume of raw sequence data, which need to be processed to give meaning information. Numerous bioinformatics tools have developed to support the different steps of the process, and they can be classified under the following categories: quality control, alignment, quantification, and differential expression (Wang *et al.*, 2009; Zhao *et al.*, 2014a). Although it is the dominant transcriptomic technology, RNA-seq has its own limitations such as introducing bias during the cDNA library construction and RNA amplification stage, and the high cost for low input RNA-seq.

Making Sense of Transcriptome

After obtaining the transcriptome, we need to go from transcriptome to phenotype. This will be equivalent to making sense of the transcriptome data. For example, how changes in gene expressions lead to metabolic phenotypes? There are 2 main ways of

looking at it: to map the data onto an existing database for visualization and functional analysis, or to compare the data with a baseline transcriptome data obtained earlier, such as comparing the genome-wide transcriptome profiling of cancerous tissue with the normal tissue to find out which subset of the transcriptome is up or down regulated. This can then be mapped onto metabolic pathways as differential gene expression is likely to result in differences in enzyme concentrations or to be analyzed by Gene Ontology, to gain insights into the molecular mechanism of cancer initiation and progression.

Transcriptome to Proteomics and Metabolomics. To integrate the transcriptomic data with proteomics and metabolomics is controversial due to the low squared Pearson's correlation coefficient (R^2) between mRNA and protein concentrations (de Sousa Abreu *et al.*, 2009). In bacteria, the correlation coefficient ranges from 0.20 to 0.47, in yeasts from 0.34 to 0.87, and in multi-cellular organisms from 0.09 to 0.46. The poor correlation suggests a significant role for post-transcriptional, translational and degradation regulation in the determination of protein concentrations (Vogel and Marcotte, 2012). Nevertheless, one may perform integrative analysis to understand genetic control of molecular dynamics and phenotypic diversity in a system-wide manner, such as or to probe protein splice variants in different tissues (Ning and Nesvizhskii, 2010), organisms (Bai *et al.*, 2014) and cells (Sheynkman *et al.*, 2013). A study (Low *et al.*, 2013) examining the liver transcriptome (using RNA sequencing) and proteome (using protein sequencing) from two rat strains (SHR and BN-Lx) found large number of RNA editing and splice variant, which demonstrates the power of integrating and interrogating various sources of omics data. Post-translational regulation can also be identified if certain peptides are present in the mass spectrometry analysis but are absent from the expressed genes of the RNA-seq dataset (Conesa *et al.*, 2016).

Integration of transcriptomics with metabolomics data has been used to identify pathways that are regulated at both the gene expression and the metabolite level, and many tools are capable of visualizing time-course data to see which pathways are active. This can be used to infer the changes of metabolic reaction rates (fluxes) across time or between different samples. This is commonly known as fluxomics (Niedenführ *et al.*, 2015; Winter and Krömer, 2013), which aims to study the differential movement of metabolites across metabolic network, leading to phenotypic observations. Large number of metabolites from prokaryotic and eukaryotic organism can be easily and precisely detected using mass spectrometry. MassTRIX uses a hypothesis-driven approach to annotate MS data within the genomic context of the organism under study, allowing user to interpret the metabolic state of the organism in the context of its potential and real enzymatic capacities (Suhre and Schmitt-Kopplin, 2008). Paintomics, on the other hand, takes complete transcriptomics and metabolomics datasets that are measured on different conditions for the same samples, together with lists of significant gene or metabolite changes, and paints this information on KEGG pathway maps (García-Alcalde *et al.*, 2011). To supports scientists during data analysis and interpretation phase, VANTED integrate experimental data into biological networks and providing a rich variety of simulation, analysis and visualization functionalities. It aims to achieve seven main tasks: network reconstruction, data visualization, integration of various data types, network simulation, data exploration, a manifold support of systems biology standards for visualization and data exchange (Rohn *et al.*, 2012). Sometimes more than one type of data is collected during the experiment and the Omics Integrator, which is improved from the initial SteinerNet, perform advanced integration of multiple types of high-throughput data as well as create condition-specific subnetworks of protein interactions that best connect the observed changes in various datasets. Unannotated molecular pathways might be detected as well (Tuncbag *et al.*, 2016).

Phenotypic Inference using GSEA. Gene Ontology (Ashburner *et al.*, 2000; Gene Ontology Consortium, 2001) is a set of defined hierarchical vocabulary aiming to describe genes and proteins, based on their molecular functions, biological processes, and cellular components. Molecular function is the biochemical activity (including specific binding to ligands or structures) of a gene product. Biological process refers to a biological objective to which the gene or gene product contributes. Cellular component refers to the cellular location where a gene product is active. Several genomes; such as, *Escherichia coli*, *Saccharomyces cerevisiae*, *Drosophila melanogaster*, *Mus musculus*, and *Homo sapiens*; had been annotated with Gene Ontology (GO). This allows us to use GO as a tool to analyse differential transcriptomic data (Fruzangohar *et al.*, 2017; Ho and Fraser, 2016; Kim *et al.*, 2016). Differential transcriptomes are result of statistical comparison between two transcriptomes (Trapnell *et al.*, 2013); for example, treated versus control, treatment A versus treatment B, and time point A versus time point B; and usually results in a list of differentially up-regulated genes and down-regulated genes. Recent examples of such studies are the study of gene expressions of seabuckthorn carpenter moth between room temperature and cold (Cui *et al.*, 2017), differential gene expression between the shoots and rhizomes of wild rice (*O. longistaminata*) subjected to cold stress (Zhang *et al.*, 2017), and differential gene expression between *Rhodnius montenegrensis* and *Rhodnius robustus* (de Carvalho *et al.*, 2017), potential vectors of Chagas disease. In all three studies, GO was used.

It is common to have lists of differentially expressed genes (both up-regulated and down-regulated) running into hundreds of genes. For example, a study of transcriptomic differences between thin and normal human endometrial tissue during the mid-luteal phase of the menstrual cycle (Maekawa *et al.*, 2017) showed 318 up-regulated genes and 322 down-regulated genes in the thin endometrium, compared to the control endometrium, as thin endometrium results in lower pregnancy rates due to implantation failures. The next issue facing the biologist is to make sense of these genes – which biological processes are up-regulated or down-regulated in thin endometrium compared to control?

This can be answered by Gene Set Enrichment Analysis (Subramanian *et al.*, 2005), or GSEA. The premise of GSEA is that; given that each gene within the genome is tagged with one or more GO terms; for each GO term, the number of genes in the up-regulated gene list can be analyzed to see whether the GO term occurs statistically more than random. The null hypothesis (random occurrence) is based on the proportion of genes in the genome or in a platform (such as, a microarray platform) that is tagged with a specific GO term. For example, if 10% of all human genes are tagged with “mitotic cell cycle” (GO:0000278), we will expect that 10% of the 318 up-regulated genes (or 32 genes) will tagged with “mitotic cell cycle” if null hypothesis is true. This implies that we expect 90% of the 318 up-regulated genes (or 286 genes) that are not tagged with “mitotic cell cycle”. However, if there are 45 genes out of 318 up-regulated genes are tagged with “mitotic cell cycle” (278 genes not tagged with “mitotic cell cycle”), then is the function of mitosis occurring higher than random?

Using χ^2 test, we get a p-value of 0.02, suggesting that mitotic function occurs higher than random and implying that mitotic function is up-regulated in thin endometrium compared to normal endometrium. This can be done repeatedly with each of the more than 40 thousand GO terms and each GO term that occurs more than random is known as enriched term. The result of this series of analyses is to obtain a set of enriched GO terms, which represents the phenotypic differences between the 2 samples – in this case, phenotypes that are more prevalent in thin endometrium compared to normal endometrium. GSEA has been used in many studies to deduce the phenotype changes from one sample to the next (Elgendy *et al.*, 2016; He *et al.*, 2013; Heng *et al.*, 2011; Kong *et al.*, 2014; Li *et al.*, 2017; Ling, 2011; Ling and Poh, 2014; Mühleisen *et al.*, 2017; Too and Ling, 2012; Weidner *et al.*, 2017).

Gene Regulatory Network Inference. Scientist may want to elucidate gene regulatory network (GRN) from large scale experimental data. To select the network model and fit the available data into the network's structure parameter is a crucial step for constructing the network from expression data. These network models can be classified into two major categories: those use continuous variables and those use discrete variables in the modelling process.

For models with discrete variables, GenYsis (Garg *et al.*, 2008) utilises Boolean network model which assumes the gene is in either on (active or expressed) or off (inactive or unexpressed). Although it is easy to simulate, Boolean network model is not able to capture certain system behaviours that can be captured by continuous models (de Jong, 2002). To overcome this problem, the probabilistic Boolean network (Shmulevich *et al.*, 2002) was proposed, which introduced uncertainty at each network node in the form of regulatory functions with a predefined probability. Another popular model for discrete variables is the Bayesian network model, which specifies a set of conditional independence assumptions in addition to a set of conditional probabilities, to obtain a directed acyclic graph that explicitly establishes probabilistic relationships between network nodes. Although it is classified as a model for discrete variable, Bayesian network can also be used for continuous variables (Lee and Tzou, 2009). For continuous variable, one may also develop a model based on differential equation, such as the one uses stochastic modelling for parameter identification of genetic regulatory networks in prokaryotes (Cinquemani *et al.*, 2008).

The primary concern of biologists is how to translate the inferred network into hypotheses that can be tested with real-life experiments. It is important to utilize information from multiple sources to narrow down the search space after a GRN is constructed (Mobini *et al.*, 2009). Pathway databases; such as, KEGG (Okuda *et al.*, 2008), and DAVID (Dennis *et al.*, 2003); are used to match the inferred GRN to a module or subnetwork. The module or subnetwork is then used to search for genes with similar gene expression profiles.

The advances of the high-throughput next generation sequencing technology (NGS) and the development of various bioinformatics tools allowed researchers to fit theoretical models to experimental data on gene expression profile. A study (Gluck *et al.*, 2016) mapping mouse salivary gland transcriptome data onto gene regulatory networks not only confirms known modulators involved in salivary gland morphogenesis but also reveal novel transcription factors and signalling pathways unique to mouse salivary glands.

Concluding Remarks

One of the major reasons for using transcriptomic data as the source data to elucidate phenotype is the relative advancement in experimental techniques in the area of transcriptomics compared to proteomics and metabolomics. Hence, transcriptomic data acts as a convenient proxy to proteomic and metabolomics data. Earlier studies using only transcriptomic data had been promising (Curtis *et al.*, 2012). For example, a study (Urzúa *et al.*, 2010) found 60% of the biological variability observed in spontaneous ovarian tumor rates and reproductive parameters across four mouse strains (BalbC, C57BL6, FVB and SWR) can be attributed to transcriptomic differences measured using microarrays.

However, in recent years, there is an increase in the number of studies attempting to integrate various sources of omics data, including transcriptomics, to elucidate the molecular basis of phenotypes. For example, epigenomic, transcriptomic, and proteomic data had been integrated to explain dysfunction in human hepatocyte caused by valproic acid (Wolters *et al.*, 2018). Multi-omics approach had also been shown to improve survival prediction in patients with neuroblastoma (Francescato *et al.*, 2018) and liver cancer (Chaudhary *et al.*, 2018). This has in turn triggered the development of algorithms to use multi-omics data (Mandal and Maji, 2018). Hence, it is foreseeable that with advances in high-throughput experimental techniques and improved computational algorithms, transcriptomics will be one of the data sources in a multi-omics pool to understand the why and how of phenotypes.

Transcriptome During Cell Differentiation

Introduction

The term development in animal is a very complex process in which a fertilized egg, the zygote, undergoes a series of gene-regulated changes to form a complete and adult organism. These changes involve not only cell proliferation but also specialization of the cells to become a certain cell type with a specific function. As the process begins, the single cell-zygote undergoes a series of cleavage to produce a morula (16–32 cells), blastula and gastrula in which three germ layers are formed. The three germ layers will differentiate into all organ systems in the mature organism. Development of an individual combines several different molecular mechanisms that can affect cell's number, morphology, behavior and function (Twyman, 2001). During development process there are changes as follow:

1. Cell proliferation: The number of cell increases as result of repeated cell division.
2. Cell growth: Increase in the production of molecules such as nucleotides, proteins, carbohydrates and lipids that cause an increase in cell's total volume.
3. Cell differentiation: Alteration of the cells from the stage of multipotent that can transform to any kind of cell to become more specific type with a specialized function.

All of these mechanisms are regulated by many genes and involves various gene regulatory proteins which determine time and location of the expression producing a specific protein in the embryo that directs cell behavior (Zasso *et al.*, 2018). Since multicellular organisms develop from a single cell (zigot), thus all cells contain the same genes. The question arises on how cells that contain the same genes behave differently? Therefore, for cell to behave differently during embryonic development, different set of genes are expressed in a certain type of cell. Moreover, especially in the eukaryotic cells, gene expression is much regulated by many transcription factors (Alberts *et al.*, 2015). Hence, development of an individual from zygote to adult is also governed by specific transcription factors (Kuo *et al.*, 1992). Simultaneous gene transcription analyses during development will reveal the key players in maintaining the multipotency and also key players responsible for cell differentiation to become specialized cell type with a specific function. In this article we will focus on gene expression profile during cell differentiation.

Cell Specialization During Development

After fertilization the zygote undergoes early cleavage producing blastomeres which are unspecialized. These blastomeres have characteristic to be totipotent, because they have capability to transform into all kinds of cells in the body, this includes amnion and chorion which are considered to be extra-embryonic membranes (Fig. 1). When the development occurs, cells undergo not only multiplication but also differentiation producing cells with a specialized function. After early cleavage of the zygote producing 2–4 blastomeres, the number of cell increases to form morula-like structure called morula containing 16–32 blastomeres (Moore and Persaud, 2008). The blastomeres then differentiate into blastocyst with two different groups of cells. The first is the inner cell mass which will develop into embryo proper and amnion and the second population is the trophoblast which will develop into the chorion and part of the embryo called the placenta. The inner cell mass cells have characteristic of being pluripotent which mean these cells have potency to differentiate into any cell type in the developing embryo but they no longer have capacity to develop into extra-embryonic structure derived from the trophoblast.

Cells that have differentiated into inner cell mass subsequently develop into one of the three germ layers which is the characteristic of the gastrula. The three germ layers will differentiate into specific cell type that forms organ systems (Fig. 1). The internal layer endoderm is the future of internal organs such as respiratory and digestive organs. The middle layer mesoderm will differentiate into muscles, urogenital organs and connective tissues including blood cells and vessel. The external layer ectoderm gives rise to organs in the neural system, sense organs and outer epithelium of the body (Moore and Persaud, 2008). Cells in the three germ layers have characteristic of being multipotent. These cells have capacity to differentiate into many cell types but not all cell types in the embryo. Cells in the immune system and blood for instance, can differentiate into a progenitor cell with capacity to give rise only to few cells in the lineage such as lymphocytes which subsequently differentiate into lymphocyte B and T. This kind of cell is characterized to be oligopotent. Finally, some cells differentiate into precursor cells with capacity to transform only to one cell type. These cells are categorized as unipotent. The precursor cells such as hepatocytes, osteoblast and chondroblast usually have capacity to self-renewal or act as stem cell for terminally differentiated cells (Strachan and Read, 2004).

Gene Transcription During Cell Differentiation

Back to the previous question, how cells with the same genome behave differently and give rise to various cells with specific function? Obviously there are mechanisms to regulate gene expression during changes from cells with totipotent to multipotent

Fig. 1 Development of zygote (fertilized oocyte) to become an individual start from early cleavage, morula, blastula, and gastrula in which three germ layers are formed. The three germ layers undergo differentiation into various tissues and organs. Each stage of the development has its own potency whether totipotent, pluripotent or multipotent.

capacities to become specialized cell. Since development and differentiation involve cell proliferation, movement, interaction with other cells and specialization, the first important genes are the gene that encode for transmembrane molecules which is important for cell-cell adhesion and cell signaling (Alberts *et al.*, 2015; Sanchez-Arrones *et al.*, 2012). The second gene is the genes that encode for transcription factors which is important for regulating gene expression (Alberts *et al.*, 2015; Cave and Sockanathan, 2018). Regulation of gene expression during cell differentiation is also performed by epigenetic mechanisms involving chromatin modification and microRNA (Alvarez-Errico *et al.*, 2015; Huang *et al.*, 2014; Youngblood *et al.*, 2013). Differential gene expression among the cells undergoing differentiation is also dictated by signal molecules present in the environment. Signal molecules affect gene regulatory protein (transcription factor) binding to the gene promoter, thus some transcriptions are "ON" some others are "OFF" during differentiation. The presence of signal molecules also determine whether cell commit asymmetric or symmetric division to produce specialized cell (Alberts *et al.*, 2015). Some well characterized signal proteins among other things are TGF β superfamily, Wnt, Hedgehog and Notch. Gene expression profiling using cDNA microarray to analyze gene transcription (Transcriptome) during cell differentiation is a very challenging task to identify key players in the process.

Transcriptome of Cell Differentiation

The molecular mechanisms that can explain pluripotency and then differentiation from the inner cell mass of the blastocyst (embryonic stem cell, ESCs) are largely unknown. Embryonic stem cells are capable of self-renew because they have stem cell

specific factors (Hochedlinger *et al.*, 2005; Hough *et al.*, 2006) and to initiate differentiation into any cell type of the three germ layers by activation of specific sets of genes by transcription factors that are required for each specific lineage (Szutorisz and Dillon, 2005). In addition to activation by specific transcription factors cell pluripotency and differentiation is also regulated by epigenetic mechanisms (Azuara *et al.*, 2006). Chromatin structure in the ESCs is characterized by specific features which is different with that of differentiated cells (Niwa, 2007). Chromatin in the ESCs is morphologically distinct from that of differentiated cells in which in the ESCs chromatin is looser so that more gene expressed in the ESCs compare to the differentiated cells (Aoto *et al.*, 2006). In the undifferentiated cells like ESCs chromatin indicate transcriptionally active state and express large regions of the genome, probably not in specific manner and at low levels (Meshorer and Misteli, 2006). Undifferentiated ESCs also express repetitive sequences, mobile elements, as well as lineage and tissue specific genes at low levels.

According to Efroni *et al.*, the properties of ESC chromatin such as global decondensation, looser binding of chromatin proteins and enrichment of active histone modification indicate transcriptionally active chromatin and it is hypothesized that undifferentiated cells (ESCs) are globally transcriptionally more active than differentiated cells. Efroni test this hypothesis, global transcription was measured by (3H) uridine incorporation and compared between undifferentiated ESCs and 7 day neuronal progenitor cells (NPCs) derived from ESCs by invitro differentiation. The results showed that total RNA and mRNA levels were almost two-fold higher in the ESCs compared to the differentiated NPCs (Efroni *et al.*, 2008). The increase in the transcriptional activity in the in the ESCs is caused by activity of the specific set of genes that reflect global activation of the genome in the ESCs. The phenomenon that higher transcription is found in the ESCs compare to the differentiated cells is evidenced in the experiment performed by Efroni which compared transcription of 12 lineage specific genes (Fig. 2).

Identification of Genes Involved in Cell Differentiation

At the blastocyst stage, the inner cell mass (ICM) will develop into three germ layers namely the ectoderm, mesoderm and endoderm. The ICM constitutes the embryonic stem cells that are capable of differentiating into any type of cells. This formation three germ layers is the characteristic of gastrulation and marks the beginning of differentiation into organs, for instance nervous system is derived from the ectoderm, skeletal muscle from the mesoderm and digestive system from the endoderm (Moore and Persaud, 2008). One of the clear examples of cell differentiation is the development of brain from the ectoderm layer. Brain development is one of the most complicated processes during embryogenesis. In the neuroectoderm differentiation, expression of pluripotent genes such as POU5F1, SOX2, NANOG decreases and the expression of neuroectoderm genes such as POU3F1, ZNF521, and also neural epithelial markers such as PAX6 and SOX1 increase and reach the peak at day 12 post fertilization (Li *et al.*, 2017) (Fig. 3).

Analyses gene expression profiling on the potency of human embryonic stem cell (hESC) to develop into neural system based on developmental period suggesting that stage 3, which is at day 8–10 of the invitro differentiation, is the critical windows for the transition from pluripotency to the neural epithelium. Moreover, several transcription factors are identified to be involved in this stage such as PAX6, SIX3, HESX1 and ID3. Deletion of either SIX3 or HESX1 causes abnormality in the development of hESC to become neural cells (Li *et al.*, 2017). Correlation analysis of the downstream target of these transcription factor found that SIX3 negatively correlated with pluripotent genes such as NANOG. This suggests that SIX3 gene promotes neural differentiation by regulating its downstream transcription factors.

Fig. 2 Reduced global transcription in differentiated cells compared to undifferentiated cells (ESC). The differentiated cells are represented by ESC-derived neuronal progenitor cells (NPC), ESC-derived postmitotic neurons (PMN), mouse embryonic fibroblast (MEF), and immortalized mouse myoblast cell line (C2C12). Black filled boxes represent expressed genes whereas white boxes represent undetected gene expression. Modified from Efroni, S., Duttagupta, R., Cheng, J., *et al.*, 2008. Global transcription in pluripotent embryonic stem cells. *Cell Stem Cell* 2, 437–447.

Fig. 3 Expression profile of pluripotent genes (NODAL, NANOG and POU5F1) and differentiation markers such as SOX2, OTX2, and POU3F1. At the beginning of embryogenesis at day 2–4 pluripotent genes are expressed (Indicates by red color), whereas during differentiation at day 6–22 expression of pluripotent genes decrease and differentiation genes are up-regulated. Red color indicates increase in the level of expression, green indicates expression decrease. Modified from Li, Y., Wang, R., Qiao, N., *et al.*, 2017. Transcriptome analysis reveals determinant stages controlling human embryonic stem cell commitment to neuronal cells. *J. Biol. Chem.* 292, 19590–19604.

Conclusion

The development of multicellular organism starts with cell proliferation, growth and differentiation that produces specialized cells. At the pluripotent stage (stem cells) the chromatin packaging is looser so that there are more genes expressed at this stage although at low levels. When cells undergo differentiation, expression of pluripotent genes such as POU5F1, SOX2, NANOG decreases, whereas genes involved in differentiation such as POU3F1 and ZNF521 increase. At the critical windows for the transition from pluripotency to differentiated cells, there is a negative correlation between transcription factors and pluripotent genes such as NODAL, NANOG and POU5F1, but positive correlation with genes involved in differentiation such as SOX2, OTX2, and POU3F1.

Recent progress in DNA microarray and RNA sequencing have enabled large scale and high quality whole cell transcriptome analysis to be performed. When complemented with Gene Ontology, both technologies could rapidly isolate important genetic determinants for further validation by qPCR. Besides the measurement of transcription at the mRNA level, gene expressions can be quantified using reporter proteins; such as green fluorescent protein. The results of these studies are usually integrated into computational models to enable the prediction of gene expression at larger scale. The steps for doing this will be discussed in this review.

Experimental Techniques

In this section, three major experimental techniques for analyzing transcriptomic activities will be discussed, followed by a discussion on reporter proteins, which are instrumental for experimental validation of transcriptomic activity.

Reverse Transcription and qPCR. qPCR exploits the sensitivity and sequence specificity of PCR for gene expression analysis (Fig. 1) where transcriptional activities can be characterized as absolute transcripts abundance or relative quantitation between biological samples. qPCR had been used to validate results from high-throughput DNA microarray and RNA sequencing. An RNA stabilizing agent, RNAlater[®], is often added prior to cell disruption to protect RNA integrity during mRNA extraction process. TRIzol[®], a monophasic solution of phenol and guanidine isothiocyanate, is routinely used to extract total RNA. When chloroform is added to the samples homogenized in TRIzol[®], RNA is preferentially extracted into the top aqueous phase. Isopropanol is added to precipitate RNA from aqueous phase. Purified RNA in sterile, diethylpyrocarbonate (DEPC)-treated water, comprising mainly of rRNAs and tRNAs and

Fig. 1 qPCR analysis of targeted transcripts. (A) Sample preparation for qPCR. Total RNA is chemically extracted from biological sample and reverse transcribed into single-stranded cDNA molecules. Thereafter, the cDNA is used as templates for qPCR in real time thermocyclers. SYBR green bind to double-stranded cDNA during the extension process and fluorescence readings are recorded. (B) Sigmodal amplification of DNA during qPCR. A threshold is set above noise level in the exponential phase and used to determine the threshold cycle, Ct. (C) Relationship between cDNA concentration and Ct values under ideal condition, i.e., DNA exactly doubles with each PCR cycle. Hypothetical Ct values from (B) is reflected in (C) by colored circles.

about 1%–5% mRNA, is assayed for RNA integrity and quantity by spectrophotometer. Heuristically, the 260:280 nm ratio of the RNA preparation should be between 1.9 and 2.1 and that of 260:230 nm should be 2.0–2.2 as lower values may indicate the presence of contaminants. Distinct rRNA bands on agarose gel electrophoresis is indicative of good quality RNA. To generate cDNA templates for qPCR, the total RNA mRNA containing mRNA is reversed transcribed into single-stranded cDNA using random primers, dNTPs, buffer and reverse transcriptase. Depending on the expression level of the target gene, 1 ng–100 ng of total RNA may be required. Random 6–9mer primers are able to bind to any region in the RNA pool of most organisms. Other primers used for cDNA synthesis are oligo (dT)s which anneal to 3′-poly(A) tails, and sequence-specific primers to amplify targeted mRNA regions. Unlike random primers, oligo (dT)s are seldom used in prokaryotic cDNA synthesis as the poly(A) tails of prokaryotic mRNA are generally shorter (Sarkar, 1997). Although nonspecific primers may generate truncated cDNAs from internal mRNA sequence, gene expression results would not be much affected so long as qPCR primers are designed targeting the 5′-end of the mRNA. Sequence-specific primers for cDNA synthesis are commonly used for synthetic RNA standards or where analysis only involves a few gene targets.

In qPCR reaction, cDNA template, sequence-specific primers and nuclease-free water are added to qPCR master mix, comprising of DNA-binding dye (SYBR), dNTPs, magnesium and Taq polymerase, before importing into the qPCR thermocycler for gene expression measurement. qPCR could be performed in PCR tubes, 96-well or 384-well PCR plates. qPCR primers, typically 20–30 bp are designed to amplify approximately 60–150 bp of the sense strand of the target cDNA at the 5′-end. Amplicons above 150 bp usually suffers from poor PCR efficiency, resulting in gross underestimation on the number of transcripts. qPCR thermocycles are optically enabled to detect fluorescent signals. As qPCR cycle proceeds, double-stranded amplicons are generated, resulting in more PCR products for SYBR to bind which increases green fluorescence emission. Fluorescence intensity correlates directly with the amount of DNA amplicons, which is a proxy to the amount of cDNA template (mRNA transcripts). As a standard, gene expressions are calculated based on the threshold cycle (Ct) – the number of PCR cycles required for fluorescence to be at a critical value above background, which also indicates the start of PCR exponential phase. Ct values are inversely proportional to initial template amount. Variations in sampling procedures, RNA extraction, reverse transcription and qPCR reaction may significantly lead to bias and compounding error (Sanders *et al.*, 2014). To mitigate such bias, gene expression results are normalized to internal reference genes. One common practice is using constitutive housekeeping genes as the normalization reference, which are assumed to have constant expression (mRNA levels), despite several studies showing otherwise (Bustin, 2000; Dundas and Ling, 2012; Thellin *et al.*, 1999). To improve accuracy, target gene expression could be normalized to the geometric average internal control genes (Vandesompele *et al.*, 2002), which should be validated with statistical software such as geNorm, NormFinder and BestKeeper (Andersen *et al.*, 2004; Pfaffl *et al.*, 2004; Vandesompele *et al.*, 2002). The relative expression ratio of two samples could be determined using the generalized Pfaffl method as illustrated in Example 1 (Hellemans *et al.*, 2007; Pfaffl, 2001). To determine the absolute amount of mRNA transcript, a standard curve of threshold cycle number plotted against varying amount of cDNA standard, Ct versus log [cDNA], could be developed by performing qPCR on synthesized cDNA standards with six or more serial dilutions. Importantly, the synthesized standard and target cDNA should be similar in PCR efficiency, amplicon length and primer binding efficiency, ensuring that the standard curve is applicable for the gene of interest. Known amounts of synthetic RNA standards could also be spiked into the extracted RNA to account for reverse transcription bias. Recommendations on experimental design, results reporting and selection of reference genes are described in MIQE guidelines (Bustin *et al.*, 2009, 2010).

Example 1: Fold-expression Calculation. qPCR was performed to analyze how the gene expression of an efflux pump differed when cells were exposed to antibiotic. Results of the qPCR run is shown in Table 1. Here, three different housekeeping genes (Ref Gene A, B and C) were used as reference genes. “Treated” and “Control” represent the mRNA from cells with and without antibiotics treatment, respectively. For each gene, threshold cycles are the arithmetic mean of technical replicates.

The general formula for normalized relative quantities (NRQ) with multiple reference genes is,

$$NRQ = \frac{E_{GOI}^{\Delta Ct_{GOI}(\text{control}-\text{treated})}}{\sqrt[n]{\prod_0 E_{ref0}^{\Delta Ct_{ref0}(\text{control}-\text{treated})}}}$$

We assumed 100% efficient amplification and amplicon exactly doubles with every exponential phase cycle. This gives an efficiency value of 2 for both the GOI and reference genes,

$$NRQ = \frac{2^{(34.00-28.50)}}{\sqrt[3]{0.59 \times 0.84 \times 0.5}} = \frac{45.25}{0.63} = 71.83$$

The $2^{\Delta Ct}$ value of GOI is 45.25. Similarly, the $2^{\Delta Ct}$ values of reference genes A, B and C are 0.59, 0.84 and 0.5, respectively; giving the geometric mean of 0.63. Hence, the efflux pump gene increased by ~72-folds upon antibiotic exposure, implying gene up-regulation.

Table 1 qPCR analysis of gene encoding for efflux pump after exposure to antibiotics

	GOI	Ref Gene A	Ref Gene B	Ref Gene C
Efficiency	2	2	2	2
Treated	28.50	21.25	19.00	23.00
Control	34.00	20.50	18.75	22.00

Fig. 2 Schematic of a DNA microarray workflow.

DNA Microarray. The DNA microarray is a structured 2D-array of short (25–80 bp), single-stranded picomoles of DNA molecules discretely spotted or synthesized on solid surfaces (Fig. 2). These DNA molecules, also known as oligo probes, are complementary to target gene sequences for hybridization between a fluorescent labeled target DNA and the immobilized probe upon contact. Experimentally, total RNA is isolated from both test and control biological samples, and assayed for microarray suitability using capillary electrophoresis and spectrophotometry. RNA quality can be assayed by Agilent 2100 Bioanalyzer and a RNA integrity number (RIN) value of 7 or higher is considered suitable for microarray experiment. Depending on the microarray technology, cell type and nature of the study, 200 ng–20 µg of total RNA (~1 µg/µl) may be required (Kang and Chang, 2012; Ling *et al.*, 2013; Trevino *et al.*, 2007). In Affymetrix arrays, mRNA are used to generate labeled cDNAs in a one pot reverse transcription reaction. Comparatively, in Agilent arrays, mRNAs are retro-transcribed into T7 RNA promoter tailed cDNAs before converted into labeled cRNAs by the Eberwine reaction (Van Gelder *et al.*, 1990). In either workflows, the cDNA and cRNA molecules are labeled using fluorescent labeled nucleotides. Common fluorescent dyes used are the red Cy5 and the green Cy3. Following the generation of single-stranded cDNA (cRNA) molecules, equal amounts of test and control cDNAs (cRNAs) are pooled together and hybridized on the microarray slides where competitive hybridization occurs between the test and control cDNAs (cRNAs), each tagged to different fluorescent dye. The ratio of red and green intensities of each probe spot corresponds to the relative abundance of the target mRNA transcripts. These can be measured by fluorescent scanner equipped with excitation lasers and digital camera for imaging. Images are overlapped and processed to convert spot intensities into numerical values. Yellow spots are observed when transcripts from both samples are of comparable abundance. In general, genes are considered differentially expressed when test and control hybridizations exhibit at least two-fold differences. Microarray results are usually reported using MIAME guidelines by the Functional Genomics Data Society (Brazma *et al.*, 2001).

Example 2: Statistical Analysis of Microarray Results. Two-sample microarrays, also known as two-channel microarrays are used to determine differential gene expressions between two samples; such as, healthy tissues versus diseased tissues (as shown in Fig. 2). It is common for a gene to be represented more than once within a microarray for statistical calculations. In this example, we assume a hypothetical microarray of only five genes and each gene is represented by five probes. The summarized results are given in Table 2. The t-statistic of each gene and its p-value can be calculated, where n is the number of probes per gene.

$$t - \text{statistic} = \frac{|\overline{\text{Healthy}}_{\text{Gene}(i)} - \overline{\text{Diseased}}_{\text{Gene}(i)}|}{s_{\text{Healthy}} / \sqrt{n}}$$

Table 2 Microarray summarized values and statistics

Gene name	Healthy tissue signal		Diseased tissue signal		<i>t</i> -statistic	<i>p</i> -value	Significance
	Mean intensity	Standard deviation	Mean intensity	Standard deviation			
Gene A	14.09	1.703	14.82	0.023	1.242	0.2821	Not significant
Gene B	13.64	0.642	15.43	0.375	4.983	0.0076	Significant
Gene C	14.14	0.053	15.99	0.796	18.002	5.6E-05	Significant
Gene D	8.18	0.836	9.73	1.487	3.785	0.0194	Not significant
Gene E	12.72	1.102	13.39	1.227	1.413	0.2303	Not significant

The threshold (α) for determining statistical significance is taken as 0.05. From this point of view, Gene D is significantly upregulated in diseased tissue compared to healthy tissue (p -value=0.0194). However, as there are multiple *t*-tests to be carried out (one test for each gene), the total threshold will increase – when 2 and 3 *t*-tests are carried out for an experiment, the threshold increases from 0.05 to 0.0975 ($1-0.95^2$) and 0.143 ($1-0.95^3$) respectively. Hence, there is a need to maintain the overall threshold at 0.05. Bonferroni correction is a simple method, which reduces the threshold to the quotient of 0.05 and the number of statistical tests required. Here, the Bonferroni corrected threshold is 0.01 (0.05/5) as there are 5 *t*-tests required. As a result, Gene D is not significantly upregulated in diseased tissue compared to healthy tissue.

RNA-Seq. In 1977, a method to decode extracted DNA sequences at single nucleotide level was developed by Nobel Prize chemist (Sanger *et al.*, 1977). This method, based on the selective incorporation of chain-terminating fluorescent dideoxynucleotide, was the core technology in the Human Genome Project (Schmutz *et al.*, 2004). Since then, a remarkable transformation is witnessed in the field of DNA sequencing with newly-developed chemistries and chip-based analytical platforms, giving rise to second and third generation sequencing technologies (Chen *et al.*, 2013; Heather and Chain, 2016; Schadt *et al.*, 2010; Voelkerding *et al.*, 2009). These led to higher throughput, sequencing depth and reliability, enabling applications beyond functional genomics, including the transcriptome analysis of prokaryotic and higher-order eukaryotic organisms, also known as RNA sequencing (RNA-Seq) (Croucher and Thomson, 2010; Mäder *et al.*, 2011; McGettigan, 2013). RNA-Seq measures transcript abundance by repeated, direct sequencing of reverse-transcribed cDNAs. Sequence data are mapped onto a reference genome and the number of mapped reads are normalized to quantify output expression as reads per kilobase of transcript per million mapped reads (RPKM) or transcripts per million (TPM) (Mortazavi *et al.*, 2008; Wagner *et al.*, 2012). Example 3 shows the different procedures to normalize raw transcripts output into RPKM or TPM. The normalization procedures are required because sequencing depth, i.e., the number of times a sample is read, and transcript length result in higher raw output readings on the detection platform. TPM provides a more straightforward breakdown of gene expression profile, although both normalization approaches are equally accepted by the scientific community (Wagner *et al.*, 2012).

Over the years, RNA-Seq has gradually displaced microarrays for transcriptomic analysis. Without the need to hybridize to transcript complementary probes, RNA-Seq provides significant advantages over microarrays. Firstly, microarray experimental design relied on the availability of known genome sequence for chip synthesis. When genome sequences are not available, the only way forward is by using chips originally intended for other closely related specie to capture cDNA. This approach may miss out on capturing the full transcriptome profile of the target due to sequence variability. In contrast, RNA-Seq could be performed for unknown samples in parallel with whole genome sequencing to access both functional genomics and transcriptome data. This greatly reduces experiment down time while also enables the identification of novel transcript isoforms (Trapnell *et al.*, 2010). A second advantage is the reliability of transcriptome data. RNA-Seq is not affected by the non-specific hybridization of cDNA to probes. Instead, multiple reads are performed on the same sample to ensure sequence reliability. This procedure allows transcription to be accurately mapped down to single nucleotide resolution, and could be particularly useful when characterizing transcriptomes with frequent repeats. As transcript abundance is measured by direct sequencing reads, RNA-Seq exhibits a larger dynamic range of detection, with better sensitivity at both low and high gene expression levels, whereas the upper detection limit of microarray is bounded by the optical sensitivity of microarray scanner under saturating condition (blinding effect). Despite the apparent advantages, there are a few considerations on the use of RNA-Seq, namely data management and storage, speed, and cost. RNA-Seq data are typically in the terabytes range while microarray data are in megabyte range. Hence, sequencing data is inherently more complicated to work with and would require a reliable suite of bioinformatics tools for data normalization and analysis (Trapnell *et al.*, 2012). However, a typical sequencing run takes between 2 and 14 days to complete while microarray experiment could be done within a day. Microarray consumables are currently substantially cheaper than RNA-Seq consumables. In the longer run, these concerns would likely be reconciled as new sequencing platforms with higher throughput, sequence accuracy and longer read lengths are developed. Ongoing efforts to correct experimental bias and consolidate best practices in RNA-Seq would eventually pave the way for dominance of this technology in high throughput transcriptomics study (Conesa *et al.*, 2016).

In the RNA-Seq workflow, total RNA is extracted and assayed for amount and quality on spectrophotometer and Agilent 2100 Bioanalyzer. RNA requirements for sequencing are more stringent than that for microarray; at least a RIN >8 for eukaryotic cells and >9.5 for prokaryotic cells should be satisfied. Illumina also recommends intact RNA in terms of the percentage of RNA fragments >200 nucleotides (DV₂₀₀) on Agilent 2100 Bioanalyzer. A few hundred nanograms total RNA with DV₂₀₀>30% would be appropriate for downstream application. Before RNA-Seq library preparation, it is prudent to

remove unwanted rRNA transcripts which competes with mRNA for sequencing capacity. For this purpose, terminator exonuclease (TEX), which degrades only rRNA substrates with 5'-monophosphate ends, could be added to the total RNA pool (Croucher *et al.*, 2009; Sharma *et al.*, 2010). Alternatively, commercial subtractive-hybridization kits could be used to deplete rRNAs. Oligonucleotide probes on magnetic beads support are used to capture rRNAs by hybridization, followed by subsequent ethanol extraction of mRNA from supernatant after beads pull down (Croucher *et al.*, 2009; O'Neil *et al.*, 2013; Petrova *et al.*, 2017; Stewart *et al.*, 2010; Westermann *et al.*, 2016). Depending on the sequencing equipment and the purpose of the study, different methods have been developed to prepare RNA-Seq cDNA libraries, which in turn determines if the directional information of transcriptional activities could be effectively captured (Croucher and Thomson, 2010). A common workflow involves fragmenting rRNA-depleted samples by ultra-sound sonication or nebulization into 200–400 bp fragments, followed by dephosphorylation on the 5'-end and ligation with sequencing adaptor on the 3'-end. Transcript 5'-ends before re-phosphorylated with T4 polynucleotide kinase and ligated with the second sequencing adaptor. Processed transcripts are reverse transcribed using 3'-adaptor as primer to generate first strand cDNA (Westermann *et al.*, 2016). Alternatively, rRNA-depleted samples could be 3'-polyadenylated with poly(A) polymerase and then treated with tobacco acid pyrophosphatase. This effectively converts 5'-triphosphate into monophosphate for 5'-adaptor ligation. Processed transcripts are reverse transcribed using oligo(dT)-adaptor primers to generate first strand cDNA (Westermann *et al.*, 2016). Adaptors are attached stepwise in specific orientation to preserve directional information. Besides mechanical fragmentation, transpososome could be used to fragment and incorporate modified adaptors onto doublestranded cDNA in a one pot reaction known as tagmentation (Adey *et al.*, 2010; Kia *et al.*, 2017). In this process, samples are reverse transcribed and amplified to generated double-stranded cDNA, using uracil instead of thymine for second strand synthesis. The resultant cDNA molecules are transposed with sequencing adaptors and treated with USER enzyme mix to deplete the second cDNA strand, retaining only tagged single stranded cDNA. This cDNA library is selectively amplified by Phusion polymerase (Phusion polymerase do not extent well on DNA templates with uracil residues) and purified (Gertz *et al.*, 2012).

The next step in RNA-Seq involves hybridizing cDNA libraries to solid surface, typically insoluble beads or glass slide, which contains oligonucleotides complementary to the adaptors. With sufficient dilution, each bead probabilistically capture only one cDNA molecule or sparsely distributed on the glass slide. Ion Torrent and SOLiD sequencing uses bead capture while Illumina uses glass slide in the form of a flow cell. Then, captured transcripts are clonally amplified by emulsion PCR into bead-bound libraries, or by isothermal bridge amplification into clusters of DNA clones. Finally,

Fig. 3 Schematic of Illumina RNA-Seq workflow.

Table 3 Transcript abundance data from RNA-Seq

	Size (kb)	Mapped reads ($\times 10^6$)		
		Replicate I	Replicate II	Replicate III
Gene A	0.5	1.2	1.5	1.6
Gene B	1	3.0	3.2	2.9
Gene C	2	4.0	4.2	4.2
Gene D	3	2.0	1.8	2.2
Gene E	4	0.5	0.5	0.6

sequencing primers are added to initiate the actual sequencing process. Raw sequence reads are mapped to specific transcripts of the reference genome and normalized to provide accurate expression output data in RKPM or TPM. Currently, the Illumina sequencing-by-synthesis platform (SBS) is considered the most dominant next generation sequencing (NGS) technology (Fig. 3) (Greenleaf and Sidow, 2014). Other NGS platforms include (1) Ion Torrent that also works on the principle of SBS but detects H^+ proton instead of fluorescence during nucleotide addition, (2) ABI SOLiD that relies on ligation chemistry (synthesis-by-ligation), and (3) single molecule sequencing technologies from PacBio and Oxford Nanopore. For more information on the various NGS platforms, the reader is referred to comprehensive reviews published elsewhere (Heather and Chain, 2016; Mardis, 2017; Schadt *et al.*, 2010).

Example 3: RKPM and TPM Calculation. An RNA-Seq experiment was performed to determine the transcript abundance in a cell culture with three technical replicates. For simplicity, it is assumed that the cell has expressed 5 different genes. Results of the sequencing run are presented in Table 3 as raw transcript counts.

TPM is obtained after two normalization steps, first with gene size and then by sequencing depth. Sample calculation for Replicate I, Gene A with size of 0.5 kb.

$$\text{normalized seq counts} = \frac{\text{seq counts}}{\text{gene size}} = \frac{1.2}{0.5} = 2.40$$

			Mapped reads ($\times 10^6$)		
			Replicate I	Replicate II	Replicate III
1st normalization by gene size	Gene A	0.5	2.40	3.00	3.20
	Gene B	1	3.00	3.20	3.30
	Gene C	2	2.00	2.10	2.10
	Gene D	3	0.67	0.60	0.73
	Gene E	4	0.13	0.13	0.15
	Total count		8.19	9.03	9.48

Total sequencing depth of Replicate I after 1st normalization is 8.19 million reads.

$$\text{TPM} = \frac{\text{normalized seq counts}}{\text{total counts}} = \frac{2.40}{8.19} = 0.29$$

			Mapped reads in TPM		
			Replicate I	Replicate II	Replicate III
2nd normalization by sequencing depth	Gene A	0.5	0.29	0.33	0.34
	Gene B	1	0.37	0.35	0.35
	Gene C	2	0.24	0.23	0.22
	Gene D	3	0.08	0.07	0.08
	Gene E	4	0.02	0.01	0.02
	Total count		1.00	1.00	1.00

RKPM is obtained after two normalization steps in the reverse order of TPM, first with sequencing depth and then by gene size. Total sequencing depth of Replicate I before normalization is 10.7 million reads ($\text{Total seq counts} = 1.2 + 3.0 + 4.0 + 2.0 + 0.5 = 10.7$).

Sample calculation for Replicate I, Gene A (1st normalization by sequencing depth).

$$\frac{\text{seq counts}}{\text{total counts}} = \frac{1.2}{10.7} = 0.11$$

			Mapped reads ($\times 10^6$)		
			Replicate I	Replicate II	Replicate III
1st normalization by sequencing depth	Gene A	0.5	0.11	0.13	0.13
	Gene B	1	0.28	0.29	0.28
	Gene C	2	0.37	0.38	0.35
	Gene D	3	0.19	0.16	0.18
	Gene E	4	0.05	0.04	0.05
	Total count		1.00	1.00	1.00

2nd normalization by gene size for the same gene, $RKPM = \frac{\text{normalized seq. counts}}{\text{gene size}} = \frac{0.11}{0.5} = 0.22$

			Mapped reads in RKPM		
			Replicate I	Replicate II	Replicate III
2nd normalization by gene size	Gene A	0.5	0.22	0.27	0.27
	Gene B	1	0.28	0.29	0.28
	Gene C	2	0.19	0.19	0.18
	Gene D	3	0.06	0.05	0.06
	Gene E	4	0.01	0.01	0.01
	Total count		0.75	0.81	0.80

Note that RKPM can be converted to TPM by dividing by the total RKPM values. Sample calculation for Replicate I, Gene A with RKPM value of 0.22, $TPM = \frac{RKPM}{\sum RKPM} = \frac{0.22}{0.75} = 0.29$.

Reporter Proteins. Reporter proteins are fluorescent proteins, or enzymes that can convert specific substrates into colorimetric or luminescent products. To quantify gene expression, genes that encode for reporter proteins are assembled downstream of DNA promoters and transformed into the biological host of choice. This approach has been adopted to characterize promoter strengths in diverse genetic context, including bacterial, yeast, plant, mammalian cells, and cell-free extracts (Auslander *et al.*, 2012; Canton *et al.*, 2008; Chappell *et al.*, 2013; Huang *et al.*, 2010; Redden and Alper, 2015; Reeve *et al.*, 2016; Schaumberg *et al.*, 2016; Wong *et al.*, 2015). The amount of reporter proteins generated during gene expression is assumed to be proportional to background-subtracted readings measured on optical instruments; such as, flow cytometry and fluorescent plate readers. Reporter proteins could also be purified and quantitated to obtain calibration plots. Direct quantification of gene expression by reporter proteins circumvent the need to isolate mRNA from cell cultures, a procedure that is often time consuming, labor intensive, costly and prone to human error. For this reason, the use of reporter proteins is preferred over qPCR for quantifying gene expression, especially for the large-scale validation of DNA promoters. Importantly, results from this approach reflects the combined effect of transcription, translation and post-translational activities, rather than mRNA transcription alone. Incorporating the results of reporter protein outputs into computational models could give estimate of the amount of transcript produced. This will require key modeling parameters, including the rates of mRNA degradation, protein maturation, protein degradation, and cell growth (Canton *et al.*, 2008; Milo *et al.*, 2010). Reporter proteins could also be used for functional analysis. For example, promoter sequences could be mutated and then assayed for changes in gene expression. When complemented with DNA sequencing, this procedure could rapidly identify core promoter regulatory regions and develop synthetic promoter libraries of varying strengths (Alper *et al.*, 2005; Hartner *et al.*, 2008; Rud *et al.*, 2006; Siegl *et al.*, 2013).

Due to the ease of use, fluorescent proteins are among the most commonly used reporter proteins in gene expression studies. The superfolder green fluorescent protein (sfGFP) in particular, is a variant of wild type GFP with unmatched performance in terms of folding kinetics, solubility and tolerance to high temperature and chemicals (Pédélec *et al.*, 2006). A major limitation of GFP and its variants is the need for molecular oxygen as cofactor during fluorophore formation; thus, restricting its application to aerobic organisms. Flavin mononucleotide-based fluorescent proteins (FbFP) was developed for use in both aerobic and anaerobic condition but the low output fluorescence remains a technical hurdle to widespread adoption (Drepper *et al.*, 2007). For anaerobic organisms, non-fluorescent reporters such as light emitting luciferases and absorbance changing enzymes are still commonplace. Popular examples of enzyme-based reporter proteins include β -galactosidase, β -glucosidase and β -glucuronidase (Partow *et al.*, 2010; Siegl *et al.*, 2013). The recent development of Spinach2, an RNA aptamer that binds to 3,5-difluoro-4-hydroxybenzylidene-imidazolinone (fluorophore mimic of GFP), provides an exciting platform to study gene expression at the mRNA level *in vivo* (Strack *et al.*, 2013).

Bioinformatics Analysis/Applications

Bioinformatics can be applied to the study of transcriptional activities in two major ways – (1) the prediction of gene expression using sequence features (such as, response elements in promoters) or from the expression of other genes, and (2) constructing mathematical models for further analyses.

Predicting Gene Expressions. In prokaryotes, functionally related genes are often regulated by a common promoter and a set of enhancers, forming an operon. Hence, expression of genes within the same operon tends to be correlated (Sabatti *et al.*, 2002). This is supported by a study (De Hoon *et al.*, 2004) showing that genes within operons show higher correlation than genes across operons. Using expressional correlation, De Hoon *et al.* (2014) can predict whether the genes are from the same operon, with 79.9% accuracy. This concept of expressional correlation from genes within the same operon has been used to improve microarray analysis by noise reduction (Xiao *et al.*, 2006). However, the relative position of the genes within the operon may affect expression. A study on *Streptomyces coelicolor* operons found that the expression of genes decreases along the relative position on the operon by normalizing expression of all genes in the operon to that of the first gene in the operon (Laing *et al.*, 2006) but this expression decline is not statistically significant up to the 5th gene on the operon but this is not observed in *Escherichia coli* where the expression of all genes in the operon is constant regardless of position. However, a study using synthetic operon found that gene expression increases linearly with the distance from the start of a gene to the end of the operon (Lim *et al.*, 2011). Nevertheless, these studies suggest that expression of genes within the same operon can be predicted by knowing the expression of one of the genes within the operon, subjected to species-specific variability as in the case of *S. coelicolor*.

In both prokaryotes and eukaryotes, several genes may be activated by the same transcription factor. Like the reason why genes within the same operon is likely to be expressional correlated, a set of genes activated by the same set of transcription factors are also likely to be expressional correlated. Binding of transcription factors to the promoter may affect chromatin accessibility (Lamparter *et al.*, 2017), leading to correlated expression patterns from genes affected by the same transcription factors (Mahdevar *et al.*, 2013). A study (Zhang and Li, 2017) examining more than 1000 human transcription factors found that transcription factor usage can be used to predict gene expression level (r^2 of up to 0.617). Genes with similar sequence features in the promoter sequence may also exhibit correlated expression profiles. For example, it has been shown that genes with dioxin-response element in their promoter demonstrate correlated expression (Kim *et al.*, 2006). Similar cases have also been discovered in other response elements; such as, immune response (Care *et al.*, 2015). It is plausible to conceive that several genes must be expressed in response to a given stimulus (Kim *et al.*, 2003), and the regulatory signaling of such stimulus may involve the same set of transcription factors or response elements.

This is supported by a previous study examining the functional aspects of genes with correlated expressions and found that genes with correlated expression demonstrate functional correspondence (Reverter *et al.*, 2005). Moreover, a study on transcriptomics (Ling *et al.*, 2008) also found large number of genes that are correlated. Hence, it may be possible to predict entire transcriptome from known expression of a handful of genes by constructing gene co-expression network. This concept is demonstrated by a study (Ling and Poh, 2014), which uses the expression values of 59 genes to predict the expression of the entire *E. coli* transcriptome. The correlation between predicted and actual expression value is 0.467, which is similar to the microarray intra-array variation. This suggests that intra-array variation accounts for a substantial portion of the transcriptome prediction error and further strengthen the potential of this approach with more reliable experimental data. Ling and Poh (2014) demonstrated the application of their predictive model using a case study – hydrogenase 2 maturation endopeptidase (hybD) can affect the efficiency of hydrogenase 2, a critical enzyme in hydrogen production during glucose (Maeda *et al.*, 2007) or glycerol fermentation (Trchounian *et al.*, 2013). The model predicted 87 genes significantly affected by the 56% knockdown of hybD, and was subjected to Gene Ontology Enrichment Analysis (Zheng and Wang, 2008). All 5 significant molecular functions enriched were of carbon/sugar transferase-typed activity, which corresponds to the expected activity as previously described (Maeda *et al.*, 2007; Trchounian *et al.*, 2013). Knowing that 56% knockdown of hybD significantly affects the expression of 87 genes, it is then possible to ask for the range of hybD expression variation that will not significantly affect any other genes; that is, the expression buffer of hybD. Using 10% stepwise changes of *hybD* from 100% knockout to 2x over-expression the number of affected genes is symmetrical and fits a quadratic model and solving the roots of the quadratic model, the expressional buffer of hybD in *E. coli* MG1655 is estimated to be 73.88% and 124.52% from its average expression (Fig. 4).

Two sequence features of the gene, GC content and codon usage, have been found to be useful in predicting gene expressions. In a study of more than four thousand human promoters across eight different cell lines (Landolin *et al.*, 2010), it was found that the GC content of promoters can be predictive of gene expression as promoters high in GC content (more than 50% GC) demonstrating constitutive expression and promoters with low GC content (less than 50% GC) more inclined towards cell-specific expression. This resulted in significant correlation ($r=0.43$) between promoter activity and reporter gene expression. Of the 789 genes expressed in all eight cell lines, 719 (91%) were genes with high GC promoters and only 70 (9%) were from genes with low GC promoters. Conversely, 378 of the 483 genes (78.3%) that were expressed in only one of the eight cell lines were from low GC promoters. This suggests that GC content of human promoters can be indicative of cell specificity.

However, the relative impact of GC content and codon usage on gene expression and transcript stability is a subject of debate. A study (Barahimipour *et al.*, 2015) attempted to resolve this by designing 4 yellow fluorescent protein (YFP) genes encoding the same amino acid sequence for expression in *Chlamydomonas reinhardtii* using differing GC content and codon usages. Using this, Barahimipour *et al.* (2015) found that codon usage plays a more important role in expression efficiency and transcript stability compared to GC content in *C. reinhardtii*. Expression efficiency is contributed by translational efficiency as the relative abundance between RNA and protein are highly correlated using RNA blot analysis, suggesting that expression efficiency is a result of transcriptional efficiency and the codon usage plays an important role in transcriptional efficiency. Moreover, this study also adds strength to the usefulness of transcriptomics analysis as a proxy for proteomics analysis as it depends on high correlation between transcript abundance and peptide abundance, given that it is experimentally easier to conduct transcriptomics studies (using experimental tools such as microarrays and RNA-seq) than proteomics studies (using experimental tools such as mass spectrometry).

Fig. 4 Percentage of reachable genes affected by varying levels of hydrogenase 2 maturation endopeptidase (hybD) expressions.

There are several metrics to calculate codon usages bias. These include codon adaptation index (Sharp and Li, 1987), relative codon bias strength (Das et al., 2012), relative codon adaptation (Fox and Erill, 2010), and modified relative codon bias strength (Sahoo and Das, 2014). Fox and Erill (2010) used relative codon usage bias to predict the expression levels of *E. coli* genes of more than 1000 bp, achieving a correlation of 0.489 between predicted and actual expression. Similarly, a study (Das et al., 2017) found correlation between these metrics but modified relative codon bias strength was found to have the highest correlation with transcriptomics ($r = -0.31$) and proteomics ($r = -0.44$). Although the correlations are not high, these studies do suggest the potential of using codon usage bias to predict transcriptional activities.

Modeling and Simulation. The main reason for studying transcriptional activities of a cell is to use it as a proxy for peptide/protein abundance. This in turn allows for a door towards elucidating the genetic and biochemical basis of various conditions. For example, it is the fundamental step for analyzing differential gene expression between various conditions (such as, disease versus healthy, or different treatment conditions) or across various time points (Creecy and Conway, 2015; Du et al., 2017; Herrera-Marcos et al., 2017; Kato et al., 2005; Lin et al., 2016; Liu et al., 2015), or to construct models to predict the phenotype given a transcriptomic change (transcriptome-phenotype correlation).

A biochemical reaction is commonly written as (where A, B, and C are the substrates; P, Q, and where A, B, and C are the substrates; P, Q, and R are the products are the products), with the following rate laws,

$$A \xrightarrow{\text{Enzyme}} P \text{ rate law 1} = \frac{k_{cat}[\text{Enzyme}][A]}{K_m + [\text{Enzyme}][A]}$$

$$B + C \xrightarrow{\text{Enzyme}} Q + R \text{ rate law 2} = \frac{k_{cat}[\text{Enzyme}][B][C]}{K_m + [\text{Enzyme}][B][C]}$$

Where k_{cat} and K_m are the turnover number (per unit time) and Michaelis-Menten constant (concentration) of the enzyme respectively, and $k_{cat}[\text{Enzyme}]$ corresponds to the V_{max} of the reaction (per unit time). When there is more than one substrate or product, the mechanism can take more complicated forms; such as ternary-complex mechanisms (Yang et al., 2011) or ping-pong mechanisms (Nakamura et al., 1994). However, these more complicated mechanisms will be unwieldy to be extended to enzymes using more than two substrates. In addition, these mechanisms will require a larger set of enzyme kinetics which is not easily obtainable. Hence, we propose to use an approximation where we consider the enzyme can only work when all the required substrates are present at the same location and with a random probability. Hence, the approximated rate law in generalized form can be written as

$$\frac{k_{cat}[\text{enzyme}](\prod_{i=1}^N [\text{substrate}_i])}{K_m + (\prod_{i=1}^N [\text{substrate}_i])}$$

The concentration of enzymes, which can be directly represented by the transcriptional activity of the gene encoding the enzyme, play a crucial role in the rate laws. The concentrations of both substrate(s) and product(s) over time can be defined as ordinary differential equations (ODEs) as

$$\frac{d[A]}{dt} = -\text{rate law 1} \quad \frac{d[P]}{dt} = \text{rate law 1}$$

$$\frac{d[B]}{dt} = \frac{d[C]}{dt} = -\text{rate law 2} \quad \frac{d[P]}{dt} = \frac{d[Q]}{dt} = \text{rate law 2}$$

As enzymes are the result of gene expression, the concentration of an enzyme can be modelled using ODEs developed in previous studies (Jayaraman *et al.*, 2016; Saeidi *et al.*, 2011). Briefly, expressed protein concentration from an inducible promoter can be modelled as

$$\text{For constitutive expression: } \frac{d[RNA]}{dt} = v_0 - \gamma_{RNA}[RNA]$$

$$\text{For inducible expression: } \frac{d[RNA]}{dt} = v_0 + \frac{v_{max} + [inducer]^n}{K_m + [inducer]^n} - \gamma_{RNA}[RNA]$$

$$\text{For repressible expression: } \frac{d[RNA]}{dt} = v_0 + \frac{v_{max}}{K_m + [repressor]^n} - \gamma_{RNA}[RNA]$$

$$\frac{d[Enzyme]}{dt} = \frac{d[protein]}{dt} = \beta[RNA] - \gamma_{protein}[protein]$$

Where v_0 and v_{max} are the baseline and maximum expression (concentration per second) of the promoter, K_m is the Michaelis-Menten constant (concentration), n is the Hill coefficient, β is the relative ribosome binding site (RBS) strength (Wang *et al.*, 2017), and γ_{RNA} and $\gamma_{protein}$ are the degradation rates (per unit time) of RNA and protein respectively.

Once created, models can be used as both a repository of knowledge and an *in silico* platform for hypothesis testing and analysis (Ling, 2016) for the purpose of advising the experimentalist on the parameters to optimize for the optimal yield (MacDonald *et al.*, 2011). This approach had been used in several studies. For example, an enzyme pathway kinetic model of mevalonate pathway had been constructed to study the crucial steps for the production of amorphaadiene from mevalonate in *E. coli* (Weaver *et al.*, 2015). After model construction, global sensitivity analysis was carried out to determine which of the six enzymes are important and found that amorphaadiene synthase expression and activity are most critical. Another study attempted to increase carotenoid production in maize also constructed an enzyme kinetic model (Comas *et al.*, 2016). While amorphaadiene from mevalonate is a linear pathway (Weaver *et al.*, 2015), many carotenoids can be synthesized from phytoene in a branched pathway with many enzymes (Comas *et al.*, 2016). Therefore, it is not obvious which enzyme expression to target to increase the yield of specific carotenoids. By analyzing the model, four independent maize lines were engineered using insights from the model analysis and validated experimentally.

These studies suggest that modeling and simulation can provide important computational tools to advise experimentalists but the success of these tools depends on the quality of characterization data from previous experiments. The quality of experimental data can be improved using bioinformatics approaches to reduce noise (Xiao *et al.*, 2006). Hence, there is a reflective process between laboratory and experimental experimentation. It can then be expected that increased experimental data will improve current computational methods, and improved computational methods will better inform laboratory experiments. This trend is likely to stay in the foreseeable future.

Survey of Antisense Transcription

Maurice HT Ling, Colossus Technologies, LLP, Singapore and University of Melbourne, Melbourne, VIC, Australia

Introduction

Antisense transcript refers to RNA transcripts that are complementary to the RNA transcript from a known gene. It has been shown that antisense transcription is widespread throughout eukaryotic genome with occurrence as high as 43% (Györfy *et al.*, 2006). Terminologically speaking, the RNA transcript transcribed from a gene is then known as the sense transcript, which will be used as template for translation. In terms of nomenclature, a common way to name antisense transcript is to prefix or suffix “AS” to its sense transcript; for example, the antisense transcript of interleukin-1- α (IL-1 α) is known as AS-IL-1 α (Chan *et al.*, 2015) whereas the antisense transcript of topomyosin I (TPM1) is known as TPM1-AS (Huang *et al.*, 2017). The first of natural antisense transcripts discovered was found in the b2 gene region of coliphage lambda (Bovre and Szybalski, 1969). An early example of antisense transcript found (Mizuno *et al.*, 1984) is complementary to the 5'-end of Outer Membrane Protein F (OmpF) RNA transcript. Upon hybridization, two consequences may occur. Firstly, the translation of sense transcript may be restricted as the abundance of single-stranded sense transcript decreases. In other cases, the splicing process may be interfered. For example, Zeb2 sense transcript hybridizes with its antisense transcript and reduces the efficiency of ribosome-binding. This results in translational inefficiency, leading to effective down-regulation of the peptide (Beltran *et al.*, 2008). Secondly, half-life of the sense transcript is likely to decrease as double-stranded RNA can be degraded by DICER (Fruscoloni *et al.*, 2003), or short antisense transcript may be incorporated into RNA-induced silencing complex (RISC) to target the complementary sense transcript for degradation (Ibrahim *et al.*, 2006).

In both cases, the abundance of resulting peptide/protein product can be modulated in the presence of antisense transcript. Moreover, it has also been suggested that sense and antisense transcripts may be independently regulated (Goyal *et al.*, 2017); hence, adding another layer of translational regulation. It has also been shown that antisense transcripts may play a significant role in human oncogenesis (Balbin *et al.*, 2015); thus, emphasizing antisense transcription as an important field of study.

However, antisense transcripts can be broadly divided into cis-antisense transcripts, where the antisense transcript originates from the same genomic locus as its sense counterpart, and trans-antisense transcript, where the antisense transcript originates from a different genomic locus as its sense counterpart. In this article, we will examine both cis- and trans-natural antisense transcription before exploring several known cases of natural antisense transcription and their effects.

Cis- and Trans-Antisense Transcription

The mRNA, which is used for translation, is transcribed from the antisense strand of the coding sequence of the DNA; hence, has the same sequence as the sense transcript. Cis-antisense transcript is then transcribed from the sense strand of the coding sequence; as a result, is complementary to the mRNA. Trans-antisense transcripts, on the other hand, refers to antisense transcripts that originate from a different gene locus but happen to share sequence similarity for RNA-RNA duplex formation. Compared to an estimated 20% occurrence in cis-antisense transcription (Ling *et al.*, 2013), trans-antisense transcription occurs about 4% (Li *et al.*, 2008).

There can be four possible orientations (Fig. 1) that can result in RNA-RNA hybrids between cis-antisense/sense transcript pairs (Wang *et al.*, 2005). Of these four different orientations, head-to-head and tail-to-tail, also known as divergent and convergent respectively (Villegas and Zaphiropoulos, 2015), are common orientations (Lavorgna *et al.*, 2004; Osato *et al.*, 2007). Head-to-head orientation (Fig. 1(A)) is likely to result in occlusion of the ribosome-binding site (Osato *et al.*, 2007) and this results in reduced efficiency of ribosomes to bind to the mRNA transcript to start translation. This in turn leads to reduced rate of peptide formation. However, it is also possible that head-to-head sense/antisense can lead to increased peptide levels in some cases. For example, antisense transcript of mouse ubiquitin carboxy-terminal hydrolase L1 (*Uchl1*) gene can activate polysomes for increased translation of *Uchl1* under specific stress conditions (Carrieri *et al.*, 2012), resulting in unilateral increase in peptide level without the corresponding increase in mRNA level. Tail-to-tail orientation (Fig. 1(B)) is commonly found in sense/antisense pairs with either similar polyadenylation tails (Gu *et al.*, 2009; Zubko *et al.*, 2011) or 3' untranslated regions (Swaminathan and Beilharz, 2016). When tail-to-tail sense and antisense RNA are transcribed at the same time, this can result in collision and stalling of RNA polymerase at the 3' end, which allows the free 5' end of the antisense transcript to bind to nascent sense transcripts in the nucleus (Dang *et al.*, 2016). In the cytoplasm, tail-to-tail sense/antisense duplex can also result in Dicer-2 processing, leading to silencing of both sense and antisense transcripts (Russo *et al.*, 2016). Full overlap (Fig. 1(C)), known as embedded, occurs when the antisense transcript overlaps with the full length of the sense transcript, resulting in complete masking and protection of the sense transcript by RNase activity (Rosikiewicz and Makołowska, 2016). RNase masking occurs whenever RNA-RNA or RNA-DNA duplexes are formed; hence, can occur in all four orientations. For example, interferon- α 1 mRNA increases its stability after being partially masked by its natural antisense transcript (Kimura *et al.*, 2013). Hence, it is plausible to consider that full overlapping antisense transcript may reduce RNase degradation to a greater level than partial overlaps (head-to-head, tail-to-tail, and internal).

Fig. 1 Four possible orientations of cis-antisense/sense pairs. (A) 5' to 5' Overlap (Head-to-head), (B) 3' to 3' Overlap (Tail-to-tail), (C) Full Overlap, (D) Internal Overlap.

Detection of antisense transcripts. There are three main methods for detecting cis-antisense transcripts; namely, hybridization method (Collani and Barcaccia, 2012), antisense microarray method (Ge *et al.*, 2008), and RNA-seq identification method (Li *et al.*, 2013). Using the principle that double stranded DNA is protected against exonuclease degradation the same way that double stranded RNA is protected against RNase degradation, Collani and Barcaccia (2012) propose to reverse transcribe total RNA into cDNA for hybridization, before degradation of single strand cDNA by exonucleases. Undegraded hybridized cDNA molecules represents sense/antisense pairs, which can be identified by sequencing. Ge *et al.* (2008) removed a step from standard microarray protocol. This step elimination ensures that cDNA from antisense transcripts, instead of cDNA from sense transcripts, is complementary to the microarray probes; hence, able to use commercial microarrays to detect for antisense transcription. However, commercial microarrays is generally dependent on the sequencing status and quality of expressed sequence tags (ESTs) for a particular species. Hence, the availability of microarrays is limited to commonly studies species, which limits its use in antisense detection in new species. Next generation sequencing (NGS) is able to overcome this limitation by *ab initio* sequencing of entire RNA pool (which is commonly known as RNA-sequencing or RNA-seq), including antisense transcripts. This is the basis of NASTIseq (Li *et al.*, 2013), which uses strand-specific RNA sequencing (ssRNA-seq) of Arabidopsis and statistical modelling to identify thousands of potential cis-antisense transcripts. Furthermore, it has been well-acknowledge (Gluck *et al.*, 2016; Green *et al.*, 2017; Kukurba and Montgomery, 2015; Merrick *et al.*, 2013; Miller *et al.*, 2014; Zhai *et al.*, 2014) that RNA-seq provides higher sensitivity and resolution, and reduced biases, compared to microarray technology. Thus, RNA-seq is currently the preferred method for antisense detection (Oono *et al.*, 2017; Shao *et al.*, 2017) due to its increasing employment and gradual cost reduction.

Detection of cis-antisense transcripts differs from that of trans-antisense transcripts. For trans-antisense transcripts, an identification pipeline has been proposed (Li *et al.*, 2008). Briefly, trans-antisense/sense pairs can be detected by pair-wise sequence comparisons using either databases of known antisense transcripts; such as, NATsDB (Zhang *et al.*, 2007); or RNA-seq data sets; to identify high-quality potential sense/antisense pairs before *in silico* assessment of hybridization potential using DINAMelt (Markham and Zuker, 2005). Although NATsDB focuses on cis-antisense, it is also possible that these antisense transcripts may exhibit sufficient sequence similarity to act as antisense for sense transcripts of other gene loci; thus, making them trans-antisense transcripts as well. This is used in the detection of trans-antisense transcripts of soybeans (Zheng *et al.*, 2013). NATpipe (Yu *et al.*, 2016) is a computational tool to discover NATs from RNA-seq data by identifying potential pairs of complementary transcripts; thus, making it useful for identifying both cis- and trans-antisense transcripts. As an example, NATpipe was used to analyse RNA-seq data of *Dendrobium officinale*, a non-model plant species, and identified more than 600 thousand potential antisense transcript pairs; of which, 436 were identified as potential cis-antisense transcript pairs.

Due to the large numbers of computationally identified antisense transcripts over the years, several databases catering to antisense transcripts had been built. For example, antiCODE (see "Relevant Websites section") collated published antisense listings of more than 10 species, including mouse, human, and rice. PlantNATsDB (Chen *et al.*, 2012) (see "Relevant Websites section") had collated more than a million antisense transcripts from 70 plant species. It can be expected that existing antisense transcript databases will grow and antisense transcripts will be a feature in organism-specific databases.

Antisense is not transcriptional noise. Despite the prevalence of antisense transcription (Györfy *et al.*, 2006) and proposed biological functions (Werner, 2005; Werner and Sayer, 2009; Werner and Swan, 2010; Werner *et al.*, 2009), there were early concerns whether

antisense transcription is a form of transcriptional noise (Ling *et al.*, 2013; Werner and Berdal, 2005) due to leaky transcription. It is known that evolutionary pressure favours sequence conservation (Hutter *et al.*, 2010; Keng *et al.*, 2014; Paulsen, 2011; Siafakas *et al.*, 2005) and several studies examining the expression of sense transcripts (Bergmiller *et al.*, 2012; Jordan *et al.*, 2005) found that expression conservation is a feature between orthologous genes. Hence, the presence of expression conservation in orthologous antisense transcripts suggests evolutionary pressure and precludes the concept that antisense transcription is solely transcriptional noise. Ling *et al.* (2013) studied orthologous antisense transcripts and found evidence of expression conservation among orthologous antisense transcripts despite lower expression conservation compared to sense transcripts. This suggests the presence of evolutionary pressure in antisense expression, implying that antisense transcription is not entirely transcriptional noise. This is corroborated by a study (Nielsen *et al.*, 2014) demonstrating conservation of antisense expression in humans and how antisense transcription may be regulated (Agarwal *et al.*, 2014; Uprety *et al.*, 2016). Hence, antisense transcription is recognized as a regulatory mechanism despite weaker regulation compared to sense transcripts (Kapusta and Feschotte, 2014), which leads to further studies in various medical fields; such as, skeletal (Huynh *et al.*, 2017) and cardiovascular (Rühle and Stoll, 2016) research.

Differing Effects of Antisense Transcription

Although it is generally considered that antisense transcripts result in down-regulation of effective level of the corresponding sense transcripts, leading to reduced peptide level; this is a heuristic with many exceptions. In addition, although the expression level of antisense transcript is generally around 10-folds lower than its sense counterpart (Villegas and Zaphiropoulos, 2015) and there is positive correlation between sense expression and antisense expression, Pearson's correlation averages at 0.44 (Ling *et al.*, 2013). This is supported by another study (Balbin *et al.*, 2015) showing overall Spearman's correlation of 0.28 and Pearson's correlation of 0.41 between head-to-head sense/antisense pairs in human. On the other hand, cases of negative correlation between sense and antisense expression has been found (Xu *et al.*, 2011). In this section, four cases are reviewed to exemplify varying and non-down-regulation impacts of antisense – (1) as-ssm1 increases the transcript level of ssm1 but has no impact on the protein level of ssm1 (Ostrowski and Saville, 2017), (2) TALAM1 (the antisense of MALAT1) increases the level of MALAT1 protein by increasing the maturation rate of MALAT1 transcript (Zong *et al.*, 2016), (3) Sox4 antisense transcripts have no effect on Sox4 mRNA or peptide level (Ling *et al.*, 2016), and (4) AS1DHRS1 silences DHRS4 gene cluster by chromatin modification (Li *et al.*, 2012). Taken together, this suggests that down-regulation of peptide levels is not the sole impact of antisense transcript. Rather, the effects of antisense transcript on the eventual peptide/protein level can be complex and should be considered on a case-by-case basis.

Ustilago maydis is a fungus that infects the corn, *Zea mays*, resulting in a fungal disease called smut. *U. maydis* mitochondrial seryl-tRNA synthetase (ssm1) is a crucial enzyme for mitochondrial function and is encoded by 2448 bases. The antisense of ssm1, as-ssm1, is a tail-to-tail antisense transcript of 2057 bases (Ostrowski and Saville, 2017). The 5' end of as-ssm1 extends 20 bases into the 3'-UTR of ssm1 transcript. Hence, as-ssm1 overlaps the entire 3' end of ssm1 transcript except 411 bases of its 5' end (83.2% overlap). Using quantitative PCR, it was found that the formation of ssm1/as-ssm1 double stranded RNA duplex protects ssm1 transcript from S1 nuclease degradation but this protection does not extend to the non-duplexed 411 bases at the 5' end of ssm1. Hence, the steady-state concentration of ssm1 is significantly increased as a result of as-ssm1 protection, leading to significant differences in growth rate and virulence of *U. maydis*. However, the protein abundance of ssm1 is not significantly different in the presence of as-ssm1 using standardized Bradford Assay. This suggests that the impact of as-ssm1 is not entirely on the level of ssm1 protein but may act as a preservation role to extend the half-life of ssm1 RNA transcript, leading to rapid translation of ssm1 transcript without undergoing transcription.

Maturation of metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) RNA requires 3' cleavage, resulting in a non-polyadenylated transcript. The antisense transcript of MALAT1 is known as TALAM1 (Zong *et al.*, 2016), which hybridize to MALAT1 at the 3' end. In human genome, hMALAT1 is 8708 bases and hTALAM1 overlaps from 1551th base to the 3' end of hMALAT1 with 963 bases of the 5' end of hTALAM1 extending from the 3' end of hMALAT1. Although the expression of MALAT1 is correlated to the expression of TALAM1 across different cell types, quantitative PCR shows that the TALAM1 transcripts in HeLa cells is about 290-times less abundant than MALAT1 transcripts. Using actinomycin D chase experiment, TALAM1 half-life drops from about 8 hours to about 3 hours in MALAT1-depleted cells (depleted using phosphorothioate internucleosidic linkage-modified DNA antisense oligonucleotides) compared to control cells. This suggests that MALAT1 confers protection to its antisense transcript despite a protection ratio of only 0.34% due to the relative abundance between MALAT1 and TALAM1. The reverse is also true – TALAM1-depleted cells shows significant reduction in the abundance of mature 3' non-polyadenylated MALAT1 RNA transcript while the abundance of nascent 3' polyadenylated MALAT1 RNA transcript is significantly increased. This suggests that MALAT1/TALAM1 sense/antisense pairs are co-reliant to maintain half-life and TALAM1 has an important role in processing and maturation of MALAT1 transcripts.

Sry-related high mobility group box 4 (Sox4) is a 47 kDa transcription factor, which binds to WWCAAW sequence, and is involved in DNA binding/bending, protein interactions and nuclear import/export. More than 20 antisense transcripts of varying lengths and from different transcription start sites have been found for Sox4 in E15.5 mouse cerebral cortex using 5' RACE-Southern hybridization (Ling *et al.*, 2016). All of them are cytoplasmically co-localized using fluorescent *in situ* hybridization (FISH), suggesting that these antisense transcripts are exported out of the nucleus; hence, potentially active. However, over-expression of Sox4 antisense transcripts did not result in significant differences in the mRNA and peptide level of Sox4, which contradicted FISH results. It is known that RNA-RNA duplex, which can result from sense/antisense hybridization, may serve as

template for processing into small RNA molecules and function via RNA interference (RNAi) machinery. A small RNA molecule, Sox4_sir3, has been found to originate from sense/antisense duplex and found to play a role in embryonic brain development. This suggests that the effects of antisense transcripts may go beyond duplex formation.

Short-chain dehydrogenase/reductase family member 4 (DHRS4) on human chromosome 14q11.2 encodes the NADPH dependent retinol dehydrogenase/reductase (NRDR), which is important in metabolism and detoxification of carbonyl compounds. The antisense transcript of DHRS4, AS1DHRS4, is a head-to-head spliced antisense transcript overlapping with exon 1 of DHRS4 (Li *et al.*, 2012). DHRS4 mRNA level and NRDR protein level increase after using antisense oligonucleotides to AS1DHRS4 to reduce effective transcript abundance of AS1DHRS4, suggesting that AS1DHRS4 abundance is inversely proportional to the abundance DHRS4 mRNA, which implies that AS1DHRS4 transcript reduces the effective level of DHRS4 transcript. In addition, AS1DHRS4 duplexing with DHRS4 transcript results in histone modification and DNA methylation as revealed by ChIP assays. These led to the reduction of transcriptional activity of DHRS4 gene.

The above cases demonstrate the variety of means in which antisense transcript can affect the abundance and half-life of the sense transcript which may or may not lead to significant changes in the abundance of resulting peptide/protein. The reverse can also be true – antisense transcript may affect the abundance of resulting peptide/protein without significant changes to the abundance of the sense transcript. Hence, suggesting a separation between transcription and translation. More importantly, these cases illustrate that antisense transcript can function at various levels. At the first order level, antisense transcript forms RNA-RNA duplex with its sense transcript but this does not lead to a uniform reduction of effective sense transcript. At higher order, antisense expression may lead to a range of other effects; such as, RNA interference and changes at the epigenetic level; which must be considered on a case-by-case basis.

Collectively, this illustrates the myriad of roles played by antisense transcripts. It is clear the roles played by antisense goes beyond initial expectations – reducing the abundance of sense transcripts. Even in this role, the methods used by each sense-antisense system is likely to differ significantly. Therefore, presenting antisense as an important area for on-going study. It is highly plausible that antisense transcription may be a field of study in its own rights as antisense is currently being explored for therapeutic purposes (Chery, 2016; Zarouchlioti *et al.*, 2018).

Introduction

Proteins are complex molecules with many vital roles in a cell such as signal reception, amplification and transduction. They also help to control gene expression, produce and transport molecules (Ford *et al.*, 2001; Yilmaz and Grotewold, 2010). The proper functioning of these processes is critically dependent on the protein abundance that is highly regulated in prokaryotes and eukaryotes. The proteins are involved in regulating the cellular homeostasis and other metabolic mechanisms. Therefore, to study an organism, it's crucial to understand the homeostasis and the balance between DNA, RNA and proteins. Any mutation in DNA/RNA or protein results in the disruption of the total cellular homeostasis and could lead to a disease (Leu *et al.*, 2011). Measuring the protein abundance to understand the dynamics between mRNA and protein levels has been investigated by several researchers. Here, we review experimental and predictive approaches to understand these dynamics.

Experimental Technologies for Measuring Protein Abundance

The expressions of proteins assist in regulating all the biochemical mechanism including signalling, transportation, degradation, genomic replication and translation of genomic data. The protein abundance and depletion is dealt with delicacy as it could disrupt the whole cellular biochemical dogma within cells (Steen and Pandey, 2002). Interestingly in yeast, 27% of total protein is expressed in the nucleus (Kumar *et al.*, 2002), indicating the importance of nuclear proteins abundance in replication, maintenance and repair of the genome. Furthermore, several diseases have been associated with proteins that are translocated in the nucleus. Therefore, it is crucial to correctly quantify protein to determine a disease or a type of disease for therapeutic purposes (Powers and Palecek, 2012). Several protein quantification techniques (such as immunohistochemistry, flow cytometry and ELISA) are in current use for the diagnosis of several diseases (Ferrier *et al.*, 1999; Yaziji *et al.*, 2008; Fromm *et al.*, 2009). Furthermore, techniques such as mass spectrometry (MS) (Vlahou *et al.*, 2003), proximity assays (Blokzijl *et al.*, 2010) and protein microarray (Ingvarsson *et al.*, 2008) are the emerging techniques for the protein quantification with more thorough output and more accurate quantification of multiple proteins at an instance. By so far, these protein quantification techniques have helped to recognize multiple markers for several diseases. However experimentally determining protein abundance is not as cost-effective as measuring mRNA concentration.

Researchers have measured protein abundance data using different technologies. For example, Chaemmaghami *et al.*, (2003) created a *S. cerevisiae* library by tagging each ORF with high-affinity epitope and by using immunodetection to calculate the absolute measurements of protein abundance. Newman *et al.* (2006) identified GF-tagged strains at single-cell resolution using high throughput flow cytometric experiment. Newman and colleagues measured protein abundance levels both in rich and minimal medium conditions to investigate the impact of medium in measuring protein abundance. Lee and colleagues studied the association between mRNA expression and protein abundance. The authors measured protein abundance by combining mass spectrometry with isobaric tagging (Lee *et al.*, 2011).

Determinants of Protein Abundance

Several scientists have described using mRNA concentration to predict protein abundance and activity, assuming that mRNA expression values are the main basis of protein abundances predictions (Tuller *et al.*, 2007; Zur and Tuller, 2012; Mehdi *et al.*, 2014). The mRNA expression data can be used to develop accurate models of protein abundance (Greenbaum *et al.*, 2003). Experimentally measuring protein abundance is highly complex and expensive. The mRNA expression is usually studied utilising several techniques among them is Microarray and RNAseq techniques (Zhu *et al.*, 2008). The RNA expression is intern designed by the RNA polymerases through DNA. The ribosomal proteins then translate this mRNA and translated into protein (Roeder, 1996). The new studies have shown that the RNA expression is sometimes unable to represent the actual protein expression levels within cells (Koussounadis *et al.*, 2015). Therefore, it is always complicated to identify protein expression through RNA expression. Furthermore, other factors also contribute to protein expression such as the half-life of mRNA and protein molecules, protein specificity towards cell cycle (Belle *et al.*, 2006). Other important determinants of protein abundance are relative tRNA abundance (Shah and Gilchrist, 2010), evolutionary rates (Tuller *et al.*, 2007; Zur and Tuller, 2012), folding energy and RNA binding proteins (Mehdi *et al.*, 2014).

Linear Regression Methods to Predict Protein Abundance

A number of different researchers use univariate approach to measure the correlation between predicted and actual protein abundance values (Yu *et al.*, 2007; Lahtvee *et al.*, 2017; Zur and Tuller, 2012). Tuller *et al.* (2007) developed two linear models that predict protein abundance and translational efficiency. These models are based on the mRNA expression values, relative tRNA abundance and evolutionary rate. For any transcript/mRNA/protein/ORF represented as 'x', the two predicted protein abundance models are given below;

$$\text{Tuller} - 1 : \log\text{PA}(x) = 3.97 + 0.4 * \log\text{mRNA}(x) + 10.34 * \text{tAI}(x) - 3.35 * \text{ER}(x) \quad (1)$$

$$\text{Tuller} - 2 : \log\text{PA}(x) = 3.47 + 0.63 * \log\text{mRNA}(x) + 10.89 * \text{tAI}(x) - 2.923 * \text{ER}(x) \quad (2)$$

Tuller and colleagues have shown that by comparing actual protein abundance with predicted protein abundance the above models achieve spearman rank correlation coefficients of 0.63 and 0.76 respectively.

Probabilistic Approaches to Predict Protein Abundance

Very few scientists have used non-linear approaches to predict protein abundance. For example, Tuller *et al.* (2007) used support vector machines to develop protein abundance predictor, however the accuracy of their model was lower than linear models. The non-linear regression performed by Lahtvee *et al.* (2017) explained proteins abundance with maximum of 61% of its variance.

Recently a Bayesian networks approach was shown to surpass accuracy of all available predictors of protein abundance (Mehdi *et al.*, 2014). Bayesian networks are belief networks that contain set of random variables. These variables have casual relationships with other variables that are represented as directed acyclic graphs. Mehdi *et al.* (2014) developed a probabilistic Bayesian networks models that integrate random variables from four different sources. The four data sources include mRNA values, protein abundance, mRNA sequence and mRNA/protein interaction data. Thus, their model combines different random variables measured with different technologies. The model is shown in Fig. 1 (reproduced from the work of Mehdi and colleagues) where PA(x) is a random variable that predicts the abundance of proteins (see "Relevant Websites section" to access the model). The variable 'x' represents ORF/gene/protein/molecule.

Zur and Tuller (2012) have previously shown that mRNA expressions, folding energy and tRNA adaptation index (tAI) correlates with protein abundance. In the Bayesian networks model, the authors first integrate mRNA expression variable with protein abundance variable and mRNA folding energy variable by assuming that increase in folding of a mRNA molecule will increase its expression and/or translation (Zur and Tuller, 2012). The model links RBP(x) with mRNA(x) representing the interaction of RNA binding proteins with mRNA molecule that modulates protein abundance. Here RBP(x) is a discrete valued node representing no interaction with mRNA (RBP(x)=1), maximum of two interactions (RBP(x)=2), maximum of four interactions and minimum of three interactions (RBP(x)=3) and above four interactions between mRNA and RBP (RBP(x)=4). Fig. 2(A) represents the probability of interaction of mRNA with RBP learned by the model. For example, 5.4% of mRNA molecules do not interact with any RBPs. 35.1% of mRNA interacts with maximum of two RBPs, 42.4% of mRNA interacts with maximum of 3 or 4 RBPs and 17.1% of mRNA molecules interact with at least 5 RBPs. We further note (Fig. 2(A)) that mRNAs that do not interact with RBPs possess low expression ($\mu = -0.15$) as compared to those who interact with RBPs ($\mu = -0.08, -0.04$ and -0.07).

To further represent the effect of mRNA and protein degradation on protein translation, the model links mHL(x) and pHL(x) indirectly with protein abundance node PA(x). Fig. 2(B) represent the parameters learnt by nodes mRNA and protein half-life; mHL(x) and pHL(x) respectively. The model learns parameters with separate Gaussian distributions for each random variable. The smaller half-life (node L3=False) node gets smaller standard deviation. By looking into the regression weights (β) in Table 1, we note that shorter half-life of proteins result in high mRNA folding energy and codon usage and low protein abundance (see row 2 of Table 1).

Fig. 1 Bayesian networks model predicts the protein abundance. Reproduced from Mehdi, A.M., Patrick, R., Bailey, T.L., Boden, M., 2014. Predicting the dynamics of protein abundance. *Molecular and Cellular Proteomics* 13 (5), 1330–1340. Each feature in the model is represented as a node. Latent nodes are represented with dotted lines. The casual relationships between parents and child nodes are shown with arrows.

Predicting Protein Abundance of Nuclear Proteins: A Case Study

This review now presents a case study by using four previously developed models to derive a correlation between RNA expression and protein abundance within the cell. Specifically, we present how to predict the abundance for the proteins typical involve in cell differentiation. Because multiple diseases including various cancers are associated with cell cycle related proteins (Otto and Sicinski, 2017), therefore, our case study will explore to what extent the nuclear proteins can be quantified in each phase of cell cycle. We also investigate how best a yeast-trained model can predict protein abundance in a human cancer cell line.

Data Resources to Develop Models

Experimental protein abundance data: In this case study, we used four experimental protein abundance datasets labelled as S1, S2, S3 and S4 (see “Relevant Websites section” to data access). The data source S1 is taken from the studies of Ghaemmaghami et al. (2003). The data sources S2 and S3 are taken from the study of Newman et al. (2006). The data source S4 is taken from the study of Lee et al. (2011).

Nuclear protein localization: Huh et al. (2003), classified proteins into 22 distinct localization in *S. cerevisiae*. 1434 of these were found to be either localized into nucleus or nucleolus. We downloaded the list of these open reading frames (ORFs) from Yeast GFP fusion localization database (see “Relevant Websites section”) to define nuclear proteins.

mRNA expression data: The mRNA expression values of two large-scale datasets from the study of Ingolia and colleagues and Wang and colleagues have been averaged as described by Mehdi and colleagues are used in the case study (Wang et al., 2002; Ingolia et al., 2009). The final mRNA expression data was log-transformed prior to be used in the prediction model.

tRNA adaptation index: The tRNA adaptation index values that has been previously constructed by Mehdi and colleagues has been used in the case study (Mehdi et al., 2014).

Half-life values of transcript and protein: The half-life values (for both transcript and protein) were taken from the study of Shalem and colleagues and Belle and colleagues are used (Belle et al., 2006; Shalem et al., 2008). These half-life values were log-transformed before applying to the available models (where required).

mRNA folding energy and interaction data: The mRNA folding energy values were constructed by using the averaged PARS (parallel analysis of RNA structure) values available through the study of Kertesz et al. (2010). The mRNA-RNA binding proteins interaction data was taken from the research of Hogan et al. (2008).

Cell cycle data and analyses: The cell cycle data has been taken from Cyclebase, referred to Pramila-alpha38 set (Gauthier *et al.*, 2008; Santos *et al.*, 2015). The data has been log2 transformed and centred at zero values by Cyclebase team. To determine the location of protein in cell-cycle phases (G1, S, G2 and M, G2 and M), we first determined the predicted protein abundance in each phase separately. We then performed one-tailed t-test between the abundance of proteins in each phase with all other phases. Specifically, the t-test was performed between G1 versus all phases, S versus all phases, G2 versus all phases and M versus all phases. The proteins with p-values < 0.05 were considered as significant and labelled as maximally expressed proteins in the corresponding phase.

Human RNAseq and Proteomics data: Melanoma cell (Mel007) were locally cultured in 6-well plates at 5×10^5 cells per well for overnight. We then treated the culture with atmospheric gas plasma (AGP) for 3 minutes as described previously (Ishaq *et al.*, 2014). An 8 h after later following the above approach, total cell RNA was extracted using Trizole reagent (Invitrogen, C#15596-026) and cells were lysed in RIPA lysis buffer (Thermoscientific, C#89901) as detailed by Ishaq *et al.* (2014). Total RNA was used for next generation RNA sequencing using Illumina HiSeqTM2000 at Beijing Genomic Institute (BGI) facility, Beijing, China. The RNAseq data relative to non-treated control was fed into mRNA(x) node of the model.

Comparing the Accuracy of Available Prediction Models

Mehdi *et al.* (2014) developed two Bayesian networks models, trained on log10 (model-1) and log2 (model-2) transformed mRNA and half-life data respectively. We ran model-1 and model-2 by providing input features (mRNA expression, mRNA-RBP interactions, mRNA and protein half-life, tRNA adaptation index and folding energy). One of the advantages of using Bayesian networks model is its capability to deal with missing values. Therefore, there were many instances where the proteins have more than one missing values while predicting their abundance, therefore the nodes corresponding to missing values were unspecified. To find the correlation between predicted and actual protein abundance of nuclear proteins, we determined the Pearson and Spearman rank correlation coefficients. These correlation coefficients have been used to study protein abundance in several previous studies (Tuller *et al.*, 2007; Zur and Tuller, 2012). In practice, the Pearson correlation assumes a linear relationship between predicted and actual protein abundance. Spearman rank correlation is the non-parametric way of finding the Pearson correlation and is more useful where the strength of direction of two variables (predicted and actual protein abundance) is required. Spearman rank correlation determines if there is a monotonic relationship between predicted and actual protein abundance.

We used both models (model-1 and model-2) to determine the abundance of nuclear proteins. To determine the accuracy of the model, we used four protein abundance sources S1-S4, as described in Data Resources section to correlate with the predicted protein abundance. The correlation values (Spearman rank, Pearson) along with p-values are shown in Table 2.

The scatter plots in Fig. 3(A-D) shows the predicted protein abundance values (using model-1) and four experimental protein abundance datasets (S1-S4) along with Pearson correlation values. The scatter plot in Fig. 3(E-H) shows the correlation between predicted protein abundance (model-2) and actual protein abundance remain similar to that of model-1. Correlation using both methods are highly significant ($p\text{-val} < 0.0001$) and comparable. Thus, we displayed Pearson correlation in the Fig. 3. Table 2 shows that highest correlation was found for protein abundance sources S2 and S3 (Pearson correlation, $r > 0.7$). Sources S2 and S3 are generated under rich and minimal medium growth conditions respectively, thus representing that nuclear protein abundances are not affected by change in the medium. Sources S1 and S4 also showed high correlations ($r = 0.62$ and 0.64 for data source S1 and 0.58 and 0.59 for data source S4) however lower than S2 and S3.

We also compared our predictions with the two models (Tuller-1 and Tuller-2) of Tuller *et al.* (2007) and the results are shown in Table 2. We found that the correlation values of protein abundance models of Tuller and colleagues are slightly higher than the

Table 2 Pearson and Spearman rank correlation values of predicted and actual protein abundance

Data source	Model	Pearson correlation	p-values	Spearman rank correlation	p-values
S1	Model-1	0.62	2.2×10^{-135}	0.62	2.2×10^{-134}
S2		0.71	5.8×10^{-124}	0.68	4.5×10^{-109}
S3		0.72	5.1×10^{-120}	0.66	3.7×10^{-95}
S4		0.59	2.5×10^{-69}	0.70	1.1×10^{-105}
S1	Model-2	0.64	6.9×10^{-146}	0.64	6.2×10^{-145}
S2		0.72	6.2×10^{-129}	0.69	2.7×10^{-113}
S3		0.72	3.3×10^{-123}	0.67	4.9×10^{-98}
S4		0.59	5.4×10^{-70}	0.69	2.3×10^{-104}
S1	Tuller-1	0.68	1.3×10^{-103}	0.68	2.7×10^{-102}
S2		0.74	2.2×10^{-83}	0.72	6.0×10^{-77}
S3		0.73	4.4×10^{-76}	0.70	1.6×10^{-65}
S4		0.64	1.7×10^{-50}	0.68	0.0×10^{00}
S1	Tuller-2	0.68	8.7×10^{-105}	0.68	1.4×10^{-102}
S2		0.75	6.6×10^{-86}	0.73	1.5×10^{-78}
S3		0.73	1.0×10^{-75}	0.69	6.8×10^{-65}
S4		0.64	1.3×10^{-50}	0.68	0.0×10^{00}

Fig. 3 Correlation of actual and predicted protein abundance using model-1 (A–D) and model-2 (E–H). Pearson correlation coefficient and linear fit is also shown.

models of Mehdi and colleagues. Highest Pearson correlation, $r=0.74$ (Tuller-1) and $r=0.75$ (Tuller-2) were found by correlating their protein abundance with S2 data source. Because the models of Tuller and colleagues are not capable to run on data with missing values, their model operated only on 703 (out of 1434) ORFs to determine the protein abundance thus we believe that the models of Mehdi *et al.*, are quite useful to predict protein abundance in practice and accuracy of prediction is not significantly compromised.

Predicting Abundance of Nuclear Proteins in Cell-Cycle Phases

The models of Mehdi and colleagues are capable of operating under condition variant stages such as cell cycle process. Perturbations in cell cycle can result in cellular death leading to various diseases including cancer. It has been

previously shown that the predicted protein abundance during cell cycle phases better explains the processes involved in cell cycle as compared to mRNA values alone (Mehdi *et al.*, 2014). Therefore, predicting cell-cycle protein abundance may help to precisely characterize the role of proteins, uncovering regulation pathways. Here we evaluated the Bayesian networks model to predict protein abundance during cell-cycle process by investigating PA(x) node and providing cell-cycle mRNA expression data generated by Permella and colleagues available at Cyclebase (Gauthier *et al.*, 2008). We were specifically interested to quantify the number of proteins in each cell cycle phase. To perform quantification, we performed one-tailed t-tests of predicted protein abundance data in G1 versus all phases, G2 versus all phases, S versus all phases and M versus all phases to count number of proteins that are maximally abundant in each phase. As shown in Fig. 4, we found that 41.8% of the proteins were not found to be significantly abundant in any of the phases and their location inside cell-cycle phases could not be uncovered. Additionally, we found 16.6% of the proteins are associated with G1 phase, 15.4% S-phase, 15.5% G2 phase and 10.6% proteins were quantified into M phase. When we specifically looked the quantification of nuclear proteins in each phase, 13.4% of those were found to be highly expressed in G1 phase, 17.9% in S phase, 14.7% in G2 phase and 9.5% in M phase. Similar to previous analysis, we were not able to quantify 44.5% of the nuclear proteins in any of the phases of cell cycle.

Predicting mRNA Folding Energy Using Protein Abundance

One of the advantages of using probabilistic Bayesian networks is their ability to designate any node as input and any node as an output node. Current methods that predict folding energy of transcripts are not based on experimental data (except the Bayesian networks model of Mehdi and colleagues), therefore could lead in making inaccurate conclusions regarding mRNA folding. It has been previously shown that the prediction accuracy of mRNA folding energy of available methods is worse than random (Zur and Tuller, 2012; Mehdi *et al.*, 2014). We therefore inferred mF(x) node of Bayesian networks model to predict folding energy of nuclear proteins of *S. cerevisiae* data. For model-1, the Pearson correlation values were found; $r=0.62$, $r=0.57$, $r=0.58$ and $r=0.55$ when providing protein abundance data from data sources S1, S2, S3 and S4 respectively. We also provided data values to all other nodes of model where available. Similarly, for model-2, the respective Pearson correlation values were; $r=0.67$ for S1, S2 and S3 and $r=0.65$ for S4. Data values to all other nodes were also provided where available.

Predicting Protein Abundance in Human Melanoma Cell Line

Atmospheric Gas plasma (AGP), a source of nitric oxide (NO), reactive oxygen/nitrogen species (RONS) has been under investigation for its properties to specifically kill variety of tumor cells. Melanoma (Mel007) is the drug-resistant tumor type which lack genome sequence data study. The Bayesian networks model developed by Mehdi and colleagues has been trained on yeast data set. We aimed to test the yeast trained model to predict abundance of proteins in human melanoma cell line (Mel007). Specifically, we investigated the anticancer effects of AGP on Mel007 cells in in-vitro cell models. Using next generation sequencing (NGS) technology and Proteomics, we first experimentally detected expression of genes. We then provided expression values of genes to the model and inferred PA(x) node to predict protein abundance, all other nodes (mHL(x), pHL(x), tAl(x) and RBP(x)) were unspecified. We then correlated the predicted protein abundance with the expression actual expression values. The positive Pearson correlation was found to be 0.11 ($p\text{-value} < 0.01$). The results show that the yeast trained model is able to measure approximately 11% of the human protein abundance correctly. To predict abundance of human proteins, a new model that is trained on human data needs to be developed.

Fig. 4 Quantification of proteins in all phase of cell cycle. (A) Percentage of proteins in each phase is shown for all data. (B) Quantification for nuclear proteins in each cell-cycle shown.

Conclusions

While a number of different features have been shown to be associated with protein abundance, the available methods use very few of them. The models of Tuller and colleagues use mRNA expression, relative tRNA abundance and evolutionary rates. The models of Mehdi and colleagues use mRNA expression, relative tRNA abundance, mRNA folding energy, RBP and mRNA interactions, half-life values of transcripts and proteins. The reason for using fewer variables amongst the all determinants of protein abundance could be because of (i) availability of an insufficient data to use them in developing models, (ii) the association between these variables and protein abundance further require experimental validations.

In this review, we presented a case study by using probabilistic Bayesian networks models developed by Mehdi and colleagues and linear regression models developed by Tuller and colleagues. The models of Mehdi and colleagues link transcriptional information with protein translation and predicts protein abundance. Their models help to understand how the transcript expressions are linked with its folding and interaction with RBPs, codon usage, half-life of ORFs and protein abundance. We have particularly shown how best their models predict abundance of nuclear proteins in *S. cerevisiae* and human melanoma cell line (Mel007).

We note that the models of Tuller and colleagues use additional information of evolutionary rate. Additionally, the inability to operate on missing value data makes them less important. The quantification of proteins in each phase of cell cycle can be performed using predicted protein abundance. We have also reviewed how the available prediction models can be used to predict mRNA folding energy. For example, when correlating predicted and experimental mRNA folding energy by using models of Mehdi and colleagues, we found a maximum Pearson correlation of only 0.67, challenging further research in this area.

Identification of Proteins From Proteomic Analysis

Zainab Noor, Abidali Mohamedali, and Shoba Ranganathan, Macquarie University, Sydney, NSW, Australia

Introduction

The identification of proteins in a biological system is one of the cornerstones of the study of biological systems. Proteins are biopolymers (polypeptides) transcribed from DNA, made up of a set of 20 amino acids and are the functional elements in a biological system. The combinations of these amino acids in a sequence gives rise to each proteins' unique shape, structure and hence function. In addition, in higher pro- and eu-karyotes, these polypeptides can be modified post-translationally (PTMs) to form even more complex structures and functions (Ngounou Wetie *et al.*, 2014). Indeed, most PTM's have given rise to their own fields of study such as glycomics (sugar polymers on polypeptides), phosphoproteomics (phosphate molecules attached to amino acids), among others. Proteins can be identified in one of two ways: i) through their structure and shape – usually performed by tagged antibodies (Kingsmore, 2006) or ii) by sequencing the protein- usually done by mass spectrometry (MS). Often, proteins identified by MS are validated using an antibody approach to ensure the accuracy of identification especially in critical applications such as biomarker discovery (Lindskog, 2015; Marx, 2013). After the discovery of human genome profile, both, antibody and MS-based techniques have been utilized to create the map of the human proteome, e.g. Human Protein Atlas (Uhlen *et al.*, 2015) and Human Proteome Map (Kim *et al.*, 2014), respectively. This article will focus on protein identification by mass spectrometry.

Mass Spectrometry Strategies

There are two different strategies for the identification of proteins using MS, 'Bottom-up' proteomics or 'Top-down' proteomics. In the bottom-up method, proteins are digested into smaller sized peptides prior to ionization and mass analysis and consequently reassembled *in silico* to infer identity. This strategy is highly advantageous in case of complex samples of abundant proteins that require efficient and sensitive separation. In the top-down method, proteins are subjected to ionization and fragmentation in the intact form without digestion and passed through mass analysers often in tandem. This method determines the complete characterization of protein isoforms and post-translational modifications for small to medium-sized proteins. Both of these strategies can be employed for protein identification depending upon the size and nature of target protein.

Mass Spectrometry-Based Protein Identification

Protein characterization and identification by MS can be performed using various approaches (see Fig. 1). More commonly, data is acquired in 'Data Dependent Acquisition (DDA)' mode, which is also known as shotgun or discovery proteomics, to identify which proteins/peptides are present in the sample. In this approach, after passing through the first mass analyzer (MS1), only the fixed number of most abundant ions are selected and get fragmented into product ions and analysed in the second analyzer (MS2) (see Fig. 2). A further two approaches, mainly used for quantification and identification of less abundant proteins, are 'Targeted Proteomics (MRM- Multiple Reaction Monitoring or SRM- Selected Reaction Monitoring and PRM- Parallel Reaction Monitoring)' and 'Data Independent Acquisition (DIA)' to perform targeted examination where proteins of interest, identified in discovery mode, are analysed for their abundance (relative or absolute) in a particular sample (see Fig. 2). The basic working mechanism of these techniques is illustrated in Fig. 2.

The identification of proteins in the last two decades has taken a significant leap and use of MS is exponentially increasing the understanding of things as diverse as truffles (Islam *et al.*, 2013) to the discovery of biomarkers in disease (Domon and Aebersold, 2006). This article focuses on the brief understanding of MS data generation, and detailed overview of MS data analysis procedures and, the tools and methods that can be applied at each step.

Fig. 1 Commonly used approaches in mass spectrometry (MS).

Fig. 2 Working mechanisms of MS-based approaches for protein identification and quantification.

Fig. 3 Workflow of MS-based protein identification.

Sample Preparation

The MS procedure starts with the sample collection and purification of proteins. Complex mixtures are often fractionated or separated using some form of chromatography (Gel electrophoresis, ion exchange etc.). The cysteine residues are then alkylated and reduced (resulting in the oxidation of methionine residues as well as carbamylation of lysine residues) (Herbert *et al.*, 2003), which results in the formation linear polypeptides.

The complex mixture of polypeptides undergoes the process of digestion more often using trypsin that cleaves the proteins at lysine or arginine residues (Huynh *et al.*, 2009) (see Fig. 3). Digestion using trypsin alone may have certain limitations and has been found to be less efficient for membrane proteins and post-translational modification (PTM) sites. To overcome this problem, proteases, such as chymotrypsin, LysC, LysN, AspN, GluC and ArgC (Giansanti *et al.*, 2016), have been analysed in parallel with trypsin and are shown to be effective in the MS analysis of large-size proteins (Low *et al.*, 2013; Benevento *et al.*, 2014; Cauci *et al.*, 2009). Similarly, *in silico* proteolytic digestion is also performed using computational tools with the same enzyme as used in the sample preparation to generate the theoretical spectral profile of the protein. Software programs such as PeptideMass (Wilkins *et al.*, 1999), PeptideCutter (Wilkins *et al.*, 1999) and Proteogest (Cagney *et al.*, 2003) perform *in silico* cleavage of polypeptides using a range of enzymes or chemical reagents to produce search or match databases.

Subsequently, the digested peptide mixture undergoes separation using chromatography and enters into the ionization source of the mass spectrometer (MS) where they are charged. The charged peptide ions traverse into the mass analyzer for separation, according to their mass to charge (m/z) ratios, in a vacuum environment, under the influence of electric/magnetic field (see Fig. 3). Not all digested peptides are able to 'fly', if they are too big, for instance.

Fragmentation

In a single-analyzer system (MS1), the separated ions generate the spectra of precursor ions when they hit a detector. In multi-analyzer systems (tandem or MS/MS), precursor ions undergo fragmentation (usually using some form of inert gas (collision induced ionization, CID)) and are converted into smaller charged fragments or product ions. The precursor ions fragment in various ways (see Fig. 3) to form unique daughter ions, dependent on the fragmentation method, e.g. b-y ions by Collision Induced Dissociation (CID) and c-z ions by Electron Capture Dissociation (ECD) and Electron Transfer Dissociation (ETD). The daughter or product ions are then analysed again in the mass analyzer to generate spectra (MS2) (see Fig. 3). For sequencing and

Welcome

Welcome to the Trans-Proteomic Pipeline (TPP) web interface. These tools and interfaces were developed and are being... Please visit www.proteomecenter.org and tools.proteomecenter.org for more information.

ANALYSIS PIPELINE

Follow these steps to convert, search, and analyze your **Tandem** data:

- 1. RAW to mzML Conversion**
Convert original .RAW files to the standard mzML input format used by the tools
- 2. Edit Tandem Default Parameters, if necessary**
It is recommended that you copy the default input file to your local directory, and edit it as necessary
- 3. Peptide Database Search and Identification**
Perform X-Tandem search.
- 4. Conversion to pepXML**
Convert original search results to the pepXML input format used by xinteract
- 5. Data Curation and (optional) Peptide Validation and Quantification**
Use Xinteract and PepXMLViewer to filter, sort, group, and highlight data based on various criteria.
You can also validate peptide identifications using PeptideProphet, and further refine peptide-level analysis and combine results from iProphet.
Calculate the relative abundances of peptides and proteins, and the corresponding confidence intervals, from isotopically-labeled XPRESS. Or use Libra to do this for isobarically-labeled data (e.g. iTRAQ).
- 6. Protein Assignment and Validation**
ProteinProphet provides a statistical model for validation of peptide identifications at the protein level.

Fig. 4 Trans-proteomic pipeline software interface for proteomic identification and analysis.

identification, the precursor ions can be subjected to peptide mass finger printing (PMF) (Thiede *et al.*, 2005) or if MS2 data is also used (which is more accurate), the sequence of the precursor ions can be determined and searched against a database (described below) (see Fig. 3). It is also called as fragment ion spectra, produced in the raw form (details of this process can be found in a review article (Aebersold and Mann, 2003)).

Data Analysis

MS data acquisition and data analysis are performed utilising several computational tools, designed explicitly for MS-based protein identification. In this article, a sample data has been acquired through public repository to demonstrate different phases of protein identification using Trans-Proteomic pipeline (TPP) by Institute of Systems Biology (ISB) (Deutsch *et al.*, 2015). This will provide an overview of data analysis, required parameters at every stage and output of results. Additionally, The OpenMS Proteomics Pipeline (TOPP) by OpenMS (Kohlbacher *et al.*, 2007) and Central Proteomics Facilities Pipeline (CPFP) (Trudgian and Mirzaei, 2012) also maintains a compilation of bioinformatics analysis tools for MS-based proteomics. With the same parameters and guidelines, data can be analysed through standalone versions of all identification programs as well.

Sample Data Set

The raw sample data was obtained from 'fission yeast' (*Schizosaccharomyces pombe*) proteome study where ~3500 proteins (71%) of the predicted genes of yeast have been analysed using MS (Gunaratne *et al.*, 2013). The experiment was performed on nano-HPLC instrument coupled to the high-resolution Orbitrap mass spectrometer and is considered to be the largest protein dataset presented for fission yeast (Gunaratne *et al.*, 2013). The dataset is available at Peptide Atlas with the accession ID 'PAe003810'.

Computation Tools

TPP has multiple pipelines for, (i) identification through protein databases, such as Comet (Eng *et al.*, 2013), Sequest (Eng *et al.*, 2008), Tandem (Craig and Beavis, 2003) pipelines, and (ii) by means of spectral libraries, such as SpectraST (Lam *et al.*, 2007) pipeline (see Fig. 4). Searching through spectral libraries can also be performed through Biblisspec (Frewen and Maccoss, 2007) for comparison purposes. The sample input data (raw files), parameter files and output files can be accessed through PeptideAtlas (see Relevant Websites section) and TPP web interface can be accessed through the provided link (see Relevant Websites section).

Step 1: Data Conversion

The data which we acquire from mass spectrometry machines is in the raw form. Generally, the formats include *.wiff, *.dat, *.yep/ *.baf, and *.raw from AB/Agilent, Agilent, Bruker and Thermo/Waters vendors, respectively. These data files are converted into standard data openXML formats such as mzXML, mzDATA and mzML. This can be performed through software, Mascot Distiller by ProteoWizard (Koenig *et al.*, 2008), Msconvert by ProteoWizard (Kessner *et al.*, 2008) and ReADW by Xcalibur (see Relevant Websites section). Conversion through any of these programs sets up the parameters for centroiding the MS scans, which are acquired in profile mode, also known as peak picking. Centroiding the data reduces the data points and lowers the sizes of files. In this example, data was available in raw format (*yeast.raw*) and was simply converted into mzML (*yeast.mzML*) format through Msconvert, under Tandem module of TPP, with centroiding (see Fig. 5).

Datasets

Links in the table go to web pages, except where "ftp" indicates that they go directly to ftp site directories. Note that the ftp subdirectories are on a separate page. If you have trouble finding anything, please ask the helpdesk.

Dataset	Description
ftp site	S. pombe ftp site root directory
DNA sequence and feature datasets	GFF files of sequence feature coordinates; files with genome sequence (FASTA), features (GFF), or both (EMBL)
CDS coordinates	Chromosomal coordinates of protein coding sequences - CDS only, or exons
Protein datasets	Protein sequence FASTA database, peptide features, properties, etc.
GO annotations	Gene ontology annotation files
Macromolecular complexes	Subunits of protein and ribonucleoprotein complexes (GO cellular component terms and annotated genes; ftp)

Fig. 6 Database FASTA file generation from (A) UniProt and (B) PomBase.

Step 2: Spectrum Identification

Spectrum identifications can be performed using one of three approaches, namely a database search, a spectral library search or a de-novo or hybrid search, each requiring their own properties and parameters. Identification through sequence databases entails searching against a broad list of potential proteins, which can be created or gathered from UniProt/SwissProt databases. Whereas a spectral library contains precursor mass/charge values, often obtained in one lab but is a prerequisite for identification through spectral matching.

Database search

For the fission yeast sample data, a database search is executed by Tandem, Sequest (the most common and freely available search engines) or Comet pipelines and respective search modules in TPP. The input files for the programs are:

- Mass spectrometry data files in mzML format, *yeast.mzML* (created in the previous step).
- Tandem parameters file, *tandem.params* (available online and may be modified).
- Sequence database file, *yeast.fasta* (including decoys).

Tandem parameter file (*tandem.params*) contains information related to:

- Search scoring scheme (*k-score*).
- File locations (path to the input/output files).

Fig. 7 Decoy sequence generation using "Decoy Database Builder."

3. Sequence database or taxonomy (name of the database file).
4. Precursor mass tolerance dependent on instrument used (default = - 2.0 to 4.0 Da).
5. Structural and isotopic modifications (according to sample run on the MS e.g. carbamidomethyl in Cysteine and/or oxidation in Methionine).
6. Peptide digestion through trypsin (fully-tryptic or semi-tryptic peptides).
7. Missed cleavages (default = 2).

Parameter files for other database search software (*sequest.params* and *comet.params*) contain similar information with very few modifications and are available with the TPP, TOPP or CPFP identification pipeline packages.

Sequence database files, usually in FASTA format (*yeast.fasta*), can be created by downloading the list of protein sequences (usually related to the target species) from UniProt (see Relevant Websites section). In this example, a single FASTA file comprising of more than 10,000 protein sequences has been formed with all the 'reviewed' proteins found against organism 'fission yeast' in UniProt and PomBase (protein sequence resource of fission yeast) (see Relevant Websites section) repositories (see Fig. 6). The FASTA file should also contain decoy protein sequences in order to perform statistical evaluation of peptide-spectrum match (PSM) (at a later stage) using target-decoy approach. To generate decoy sequences, several methods are available such as shifting the precursor m/z ratio values of *in silico* generated spectra and, randomly shuffling and reversing the database sequences (Elias and Gygi, 2010) (see Fig. 7). Different freely accessible programs and scripts have been developed to accomplish this task and are listed below:

1. DecoyPYrat by Sanger Institute generates a set of decoy sequences through reversing the database sequences (Wright and Choudhary, 2016). It is a python-based script 'decoyPYrate.py', can be downloaded (see Relevant Websites section) and run on Python ver. 3 or above (see Relevant Websites section).

The screenshot displays the 'X!Tandem Search' interface within the 'ISB/SPC Trans Proteomic Pipeline'. The top navigation bar includes 'Home', 'Files', 'TPP Tools', 'External Tools', 'Account', and 'Jobs'. The main content area is divided into several sections:

- CHOOSE MZ[X]ML INPUT FILES**: Shows a text input field with the path 'c:/TPP/data/demo/tandem/yeast.mzML' and an 'Add Files' button.
- CHOOSE TANDEM PARAMETERS FILE**: Shows a text input field with the path 'c:/TPP/data/demo/tandem/tandem.params' and an 'Add Files' button.
- CHOOSE A SEQUENCE DATABASE**: Shows a text input field with the path 'c:/TPP/data/dbase/yeast.fasta' and an 'Add Files' button. Below this is a dropdown menu labeled 'Or choose from list:' with the selected path 'c:/TPP/data/dbase/ [*]'.
- OPTIONS**: Contains a checked checkbox labeled 'Convert output files to pepXML'.
- SEARCH!**: Features a prominent green 'Run Tandem Search' button.

Yeast Pombe Ion Trap Library

May 18, 2013

This library was assembled from data contributed by many laboratories. Each library entry contains annotation specifying its origin. Additionally, a summary table of the many contributors to this library, including references, can be downloaded [here](#) (Excel file).

File - Description	Size	Link
2013_05_18_yeast_pombe_consensus_final_true_lib.tar.gz - Consensus library in plain ASCII text (msp format). This format can be used as an exchange format. It is also directly readable by some software applications, including Skyline, after unzipping.	81MB	Download
2013_05_18_yeast_pombe_nist.tar.gz - Consensus library in NIST binary format. The folder generated by extracting this package can be used directly by MS Search or MSPepSearch and by the MSPepSearch node within Proteome Discoverer.	162MB	Download
2013_05_18_yeast_pombe_spectrast.tar.gz - Consensus library in SpectraST format. These library files can be directly searched by	195MB	Download

Fig. 9 Yeast spectral library from the NIST database.

- Decoy Database Builder (DecoyDBB), a module of PeakQuant Suite, build the decoy databases by reversing, reshuffling and random generation of target protein sequences (Reidegeld *et al.*, 2008). A stand-alone version of this java-based program is available at the link (see Relevant Websites section).

X! Tandem, Sequest and Comet perform *in silico* digestion of proteins in FASTA file according to the provided parameters, generate the theoretical spectra (with precursor m/z values), followed by matching it to the observed spectra and calculates the search scores (see Fig. 8).

Spectral libraries search

Investigation of MS spectra by inquiring previously identified spectral libraries is performed by employing SpectraST search module with the following input files:

- Mass spectrometry data files in mzML format, *yeast.mzML* (created in the previous step)
- Spectral libraries, *yeast.splib* (downloaded from NIST)
- SpectraST parameters file, *spectrast.params* (available online and can be modified)
- Sequence database file, *yeast.fasta* (including decoys)

Spectral libraries can be downloaded from different public repositories. These repositories contained highly-organized data for a number of species, for example, PeptideAtlas (Desiere *et al.*, 2006), SRMATlas (Kusebauch *et al.*, 2016), ProteomeXchange (Vizcaino *et al.*, 2014), and National Institute of Standards and Technology (NIST) (see Relevant Websites section), among others. The spectral library against *S. pombe*, used in this review, is the NIST 'Yeast Pombe Ion Trap Library'. This consensus library is created using spectra generated in different scientific laboratories (Pointner *et al.*, 2012; Gunaratne *et al.*, 2013), and is available at the link (see Relevant Websites section) (see Fig. 9). The different data formats of spectral libraries are *.blib, *.clib, *.msp, *.sptxt, and *.splib. SpectraST usually works with libraries in the *.splib format.

SpectraST parameter file contains information related to:

- File locations (path to input/output files)
- Precursor m/z tolerance (default=3.0)
- Structural and isotopic modifications
- Accept/ignore the abnormal spectra
- Peak selection options

SpectraST (see Fig. 10) matches the peaks in experimental and library spectra and calculates the dot product or *dotp* score (similarity measure). Values of *dotp* range from 0 to 1, where 0 means poor similarity and 1 means a perfect match.

Fig. 10 Trans-proteomic pipeline spectraST search module and parameters.

Search output

The output result of both the database and spectral library search includes a *yeast.log* and a *yeast.pepXML* files, which contains the following information (see Fig. 11):

1. Query spectra
2. Retention time values
3. Identified peptides and their ranks
4. Search scores
5. Dot product scores (similarity significance)
6. Sensitivity and error scores

De Novo and hybrid search approaches

Besides database and spectral matching, *de novo* sequencing, i.e. explicit translation of spectral peaks into the sequence, and hybrid approach, i.e. a combination of database search and *de novo*, are also available but are not commonly used, only utilized in specific cases. PepNovo by Centre for Computational Mass Spectrometry (CCMS) (Frank *et al.*, 2007) and Sequit by Proteome Factory (Demine and Walden, 2004) are highly efficient and compatible tools for *de novo* sequencing. These approaches have been discussed elsewhere (Islam *et al.*, 2017b). Guten Tag by Yates Laboratory (Tabb *et al.*, 2003) and Spectral Networks by CCMS (Bandeira, 2011) are competent tools for identification of peptides through a hybrid approach.

Step 3: Peptide-Spectrum Match Statistical Validation

Peptide-spectrum match (PSM) validation is performed through PeptideProphet (Ma *et al.*, 2012), iProphet (Shteynberg *et al.*, 2011) and PTMProphet (Shteynberg *et al.*, 2012) modules of TPP which estimates the false discovery rates (FDRs) for PSMs.

Additionally, standalone tools such as Scaffold by Proteome Software (Searle, 2010) and MAYU (Reiter *et al.*, 2009) can also be used for the statistical assessment. PeptideProphet is executed by assigning probabilities to PSMs and takes *yeast.pepXML* search output files as input. It takes into account the entire search score profile from pepXML files against correct and incorrect peptides and generates a 'correct match' probability for each result. On the TPP web interface, the program can be found in the 'Analyze Peptides' section of TPP tools (see Fig. 12) and run either in default mode or with other advanced options available for PeptideProphet such as considering pI information, phosphorylation or other PTMs information, and spectra RT values, among others. To filter out the correct identified peptides, significance level or 'PeptideProphet probability' is set to 0.05 (i.e. the probability of a peptide to be selected as correct by chance is less than 0.05) and minimum length of peptide is set to seven (7).

The output files generated by running PeptideProphet, on both Tandem and SpectraST files, are usually saved with the name *interact.pepXML*. These files comprise of statistical evaluation values for each of the peptides along with the peptide sequences and protein names from the protein sequence database file (*yeast.fasta*). The list of all the validated peptides can be viewed in TPP interface in tabular form where it can be sorted in a number of ways such as by probability, dot product values, protein names and *m/z* values (see Fig. 13). The peptides with the probability score close to 1 are most likely to be correct.

The program iProphet or InterProphet performs the statistical refinement of the PeptideProphet results. It takes the *interact.pepXML* files as input and generates *interact.ipro.pepXML* files with the refined probability score (see Fig. 13), also called as 'iprob' and can be analysed in a similar way as PeptideProphet results. The files, *interact.pepXML* and *interact.ipro.pepXML*, can also be viewed in other text format programs for a detailed overview.

Step 4: Protein Inference and Validation

In order to correctly infer the protein identity using the identified peptides, which were actually present in the sample, is a highly extensive task. The presence of a single peptide sequence in multiple proteins complicates the process and needs a comprehensive statistical assessment. Most commonly programs used to accomplish this task are DTASelect (Tabb *et al.*, 2002), DBParser by Mascot Distiller (Yang *et al.*, 2004), Scaffold by Proteome Software (Searle, 2010) and ProteinProphet (Nesvizhskii *et al.*, 2003) by TPP. Fig. 14 Statistical validation at the protein level using ProteinProphet.

the current example, ProteinProphet was used which utilizes the statistical values and peptide/protein related data from *interact.pepXML* and *interact.ipro.pepXML* files and generates the following information in a file called as *interact.ipro.protXML* (see Fig. 14):

1. List of identified proteins
2. List of identified peptides in each protein
3. Probability score against each identification
4. Calculated mass values for peptides
5. Number and nature of ions/transitions against each peptide entry (b/y ions)
6. Number of unique peptides, proteins and single hits

Step 5: Validation through HUPO Metrics

The Human Proteome Organisation (HUPO), recognising the need to standardise the parameters and conditions to allow for accurate validation of protein identifications, proposed a set of matrices that would increase confidence in MS results, primarily for 'missing proteins' (Baker *et al.*, 2017). A systematic approach to evaluating the quality of proteomics data can be obtained from Islam *et al.* (2017a) which encompasses the most recent communally accepted metrics (Omenn *et al.*, 2016) (see Relevant Websites section). Briefly, HUPO recommends applying a threshold of $\leq 1\%$ global FDR at the protein level, having two or more non-nested peptides that are ≥ 9 amino acids long in addition to other checks, such as calibration of instruments and reporting all FDR's, scores, databases, parameters (instrument and search) used and finally depositing data in a public repository. Although this is only applicable for missing proteins, applying such metrics in all protein identifications can greatly improve the confidence in proteins identified.

Step 6: Data Storage in Public Repositories

In order to eliminate the computational expense and data redundancy, all the mass spectrometer raw data and annotated files related to the specific sample, are encouraged to be submitted to publicly available data repositories. Some of the most common sources of MS-based proteomics identification data (other than above-mentioned library resources) are PRoteomics IDentification (PRIDE) by EBI (Vizcaino *et al.*, 2016), Computational Proteomics Analysis System (CPAS) (Rauch *et al.*, 2006), Open Proteomics Database (OPD) by Marcotte Lab (Prince *et al.*, 2004) and PeptideAtlas (Desiere *et al.*, 2006). The general conditions and requirements for data submission are as follows:

1. Targeted species and sample proteome.
2. Identify the type of MS data produced (MS or MS/MS).
3. Experiment protocols and instrumentation (growth, extraction, separation, digestion and informatics).
4. Usually, all the data files such as raw, mzML, pepXML, protXML etc.
5. Publication manuscript.

Discussion and Conclusions

The process of protein identification from mass spectrometry as is observed above is an iterative process that relies heavily on computation and statistical models and prediction. This introduces a significant number of variables and thresholds and

depending on the parameters and computational algorithm or search database used (or chosen), can result in variable outcomes (Ramos-Fernandez *et al.*, 2008). In addition, the starting material, the proteins themselves, are often highly heterogeneous both in structure and sequence with the same protein having multiple forms in form of splice variants, PTM's, single amino acid variations (SAAV's), and mutations, among others. Other compounding factors such as the resolution of different MS instruments, resolution and nature of sample preparation techniques and separation methodologies, the abundance of proteins, the ability of peptides to 'fly', and others, all play a role in the successful identification of a protein (Baldwin, 2004).

Despite the above, the probability-based statistical approach used in the identification of proteins in mass spectrometry over the last two decades has made significant improvements with more robust, reproducible and reliable computational methodologies allowing for greater confidence in data. Furthermore, improvements in quality and resolution of MS instrumentation also has had a significant impact in the identification of a large number of proteins accurately. Lastly, a communal recognition of the variability of data has led to initiatives such as that of HUPO to attempt to standardise and streamline the reporting of protein identifications and develop communally acceptable metrics for positive identification, though to date, no identification standards exist for PE1 (proteins with protein-level evidence). It is for this reason, that aside from orthogonal validation, the validation of MS data requires comprehensive and transparent reporting of all parameters and methodologies used (Martens and Hermjakob, 2007).

Further Analysis after Protein Identification

Upon accurate identification and validation of MS data, the list of identified proteins can be further processed through a series of post-data analysis computational and informatics pipelines to allow annotation (Islam *et al.*, 2014), quantification, expression or network analysis, gene ontology analysis, among others. One of the primary ways to look at detailed annotation is to copy the protein ID from the output table (step 4) and search against UniProtKB database – one of the biggest protein databases. UniProtKB has accumulated, for every protein, the information related to its function, taxonomy, modifications, interactions, families and domains, among others. It also contains cross-references to additional databases such as GO for gene annotation, IntAct, STRING and MINT for molecular interactions, RCSB PDB for 3D structures against target protein sequence, SMART, Pfam and PROSITE for family and domains, Ensembl database for phylogenetics and KEGG for network analysis. The detailed post-data analysis methodologies and tools are beyond the scope of this article but have been discussed elsewhere (Bessarabova *et al.*, 2012; Schmidt *et al.*, 2014). Often the information from a post-MS data analysis is used to inform and select candidates for further orthogonal validation of the identification.

Orthogonal Validation of Identity

The most efficient and commonly acceptable way to confirm the identity of a protein is to use orthogonal techniques, especially in sensitive areas such as biomarker discovery (Rifai *et al.*, 2006). The most common form of orthogonal validation is that of affinity-based identification such as western blotting, ELISA or protein/peptide arrays whereas more robust or stringent applications may indeed use functional (biochemical or biological) assays (Rabilloud and Lescuyer, 2014) to validate identifications, functional annotations and identities. As a discovery and hypothesis generating tool, MS-based identification in proteomics of multiple proteins remains the most efficient and accurate as long as accepted and standardised informatics methodologies are applied.

Biographical Sketch

Zainab is a PhD student in the department of Chemistry and Biomolecular sciences (Bioinformatics group) at Macquarie University. She has been working in the area of protein structure and function analysis during her bachelors and masters' studies. Previously, she worked on identifying novel potent drug-like compounds against histone deacetylases proteins by employing *in silico* drug designing techniques. Currently, she is involved in programming-based mass spectrometry data analysis of data generated through data-dependent acquisition (DDA) and data-independent acquisition (DIA) approaches related to colorectal cancer. More specifically, she is dealing with the customization of DDA based spectral libraries to be used in DIA data analysis for biomarker discovery.

Abidali is a Lecturer at Macquarie University in the Faculty of Science and Engineering. He completed his PhD in 2010 studying, using proteomics, the effects of single mutations in mouse model on brain development in the autism spectrum disorder, Rett syndrome. He then returned to Macquarie University undertaking a post-doc to study the biology of metastasis in colorectal cancer using proteomics and to determine novel therapeutic targets and develop novel technologies to examine the plasma proteome.

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia, as well as a consultancy in industry. Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books, as well as contributed several articles to Springer's Encyclopedia of Systems Biology. She is currently the Editor-in-Chief of Elsevier's Encyclopedia of Bioinformatics and Computational Biology, as well as the Bioinformatics Section Editor for Elsevier's Reference Module in Life Sciences.

Quantification of Proteins From Proteomic Analysis

Protein Quantification – Introduction

All living biological entities rely on an intricate balance of metabolic activity, bio-molecules and non-organic molecules to maintain life. Inherent to this balance is the ability to respond rapidly to changes from within or without. Although the breadth of this response can be vast from activating enzymes to opening channels to allow ions to leave or enter, its temporal nature can be varied leading to permanent changes due to chronic signals or transient changes due to acute signals and every variation in between. One of the most fundamental changes that occur in cells is the variation in the abundance of proteins (Vogel and Marcotte, 2012) in response to external or internal stimuli. Indeed, it is well understood that although transient and rapid alterations in cells is often due to modification of the activity of proteins, sustained stimuli lead to sizeable changes in the proteome (the protein complement) of an organism due to changes in transcriptional and translational activity; therefore, protein abundance. This fact has been the source of understanding how biological systems respond to change which has led to the development of markers of change that have revolutionized medicine. An illustration is the discovery of Early pregnancy factor (EPF) as an indicator of early pregnancy (Fan and Zheng, 1997) has revolutionized early maternity practice.

Although it has been known that multiple proteins change expression in relation to stimuli (or treatment), most studies were able to measure and quantitate only a small number of proteins at a time using immunological methodologies (such as, ELISA and Western blotting). Upon the advent of mass spectrometry, researchers began to investigate how this new method could not only identify but also quantitate multiple proteins. The rapid expansion of the technologies and the development of novel label-based quantification and methodologies of label-free quantification using spectral counting led to significant advances in the field. By early 2007, it was possible to quantitate thousands of proteins in a single experiment. These methodologies had significant drawbacks especially around experiment design, technical variability, reproducibility and reliability (Bantscheff *et al.*, 2007). A more recent and powerful technique, loosely based on targeted quantification (multiple reaction monitoring), using a Data Independent Acquisition (DIA) mode on a mass spectrometer has made quantification far more reliable and robust. Fig. 1 summarises the most common methodologies used to quantitate proteins. This book article will discuss in brief detail some of the most common proteomic methodologies of protein quantification, with a particular emphasis on DIA quantification. Using an example, the article will guide a reader through setting up their own data analysis workflow and to apply statistical and experimental validation techniques to accurately quantify thousands of proteins from a biological sample.

Label-Based Quantification

The basic principle of label-based protein quantification technique is labelling or tagging of peptides/proteins with stable heavy isotopes (^{13}C , ^{15}N , ^{18}O and ^2H) and comparing the unlabelled 'light' form of the sample with labelled 'heavy' variant in mass spectrometry. In a given mass spectrum, a mass shift of 3–4 Da occurs in a heavy isoform where the ratio of peak intensities of both isoforms depict the ratio of abundances (Lindemann *et al.*, 2017). This method has been employed in studying modified proteins, membrane proteins, quantifying disturbances or perturbations in a system due to changes in proteins and effects of drugs or inhibitory compounds on protein expression. Label-based quantification is limited by the number of labels that can be applied at the same time (multiplexing) such that up to 12 samples can currently be studied simultaneously (King *et al.*, 2017).

Label-Free Quantification

Label free quantitative proteomics is an extensively used semi-quantitative approach capable of multiplexing multiple MS runs into a single experiment. This approach has wide application in high throughput applications with large individual variation and large sample size, such as in clinical proteomics. Label free quantification in such case can yield more analytical depth and higher dynamic range for quantification (Distler *et al.*, 2016).

Label free quantification is based on comparison of precursor ion intensities between MS runs, measured in terms of peak area or peak intensity after feature alignment according to retention time, m/z , charge states etc. A reproducible LC-MS system is an absolute requirement for efficient feature alignment (Norbeck *et al.*, 2005). Label free quantification requires resource intensive computational capability for feature detection and alignment (Mueller *et al.*, 2008), but unlike label-based quantification, the only limit to number of samples that can be analyzed is computational.

Regardless of platform and method adopted, label free quantification relies on extracted ion chromatogram (XIC) intensity-based quantitation or spectral counting-based quantitation. It has been observed that ion concentration correlates with ESI signal intensity; that is, higher peptide concentration in sample yields higher area under integrated chromatogram of a MS spectra. Relative area under curve/chromatogram (peak area) or peak intensity between samples can be used for relative quantitation of peptides/proteins across samples (Neilson *et al.*, 2011).

Fig. 1 Multiple approaches exist for MS based protein quantification. Labelling quantifies protein on basis of difference in signal intensities between heavy and light labelled peptides from different samples combined into a single run. Label free quantification is performed by measuring relative signal intensities between multiple sample runs. Quantifications are accomplished on DDA and DIA mode, depending on targeted and comprehensive data analysis.

Spectral counting-based quantification relies on assumption that number of tandem mass spectra are proportional to abundance of a protein, that more spectra are observed with increasing peptide concentration in the sample (Washburn *et al.*, 2001). Normalization factors relating to length and physiological properties of a peptide and its ability to be fragmented are taken into consideration (Ahme *et al.*, 2013). One challenge with combining XIC-based quantitation with DDA-based identification is finding a balance between MS (quantitation) and MS² (identification) cycling. Devoting more scanning time to peptide identification decreases the number of data points available for MS quantitation, which limits the resolution, and hence accuracy of XIC-based quantitation.

Relative Quantification

Relative quantification is the measure of change in protein expression patterns as a function of biological function, expressed in terms of ratios between different biological states. Relative quantification is measured by either of labelled-based or label-free quantification, depending upon scope of the experiment. A number of labelled-based relative quantification strategies have been developed which are characterized by their mode of action. They are broadly classified into three categories (i) metabolic labelling, biological incorporation of isotopes or labels in a cell culture; (ii) chemical labelling, integration of heavy isotopes into the proteins using isotopic reagents or isobaric tags and (iii) enzymatic labelling, labelling with heavy isotope of oxygen during hydrolysis of protein through trypsin or other proteases. Similarly, various label-free approach could be adopted for relative quantification.

Absolute Quantification

Absolute quantification is the process of measuring the exact amount of a protein in a proteome. Proteins of interest (sample proteins) are spiked with known concentrations of labelled standard peptides bearing identical sequence and physicochemical properties as sample peptides. Quantification is performed by comparing the intensities of the sample and standard peptides/proteins, where unknown quantities of sample proteins can be deduced by means of known concentrations of standard proteins. Several peptide or protein-based approaches have been designed for absolute quantification including absolute SILAC, protein standard absolute quantification (PSAQ), full-length expressed stable isotope-labelled quantification (FLEXIQuant) and quantification Concatemers (QconCAT). Similarly, in the label-free context, MRM assays use the same approach described to accurately quantify selected peptide transitions and hence infer absolute protein abundance.

Quantification Through Data Independent Acquisition (DIA)

During the last decade, most of the MS-based proteomics studies were based on a discovery-based shotgun proteomics method, run in data-dependent acquisition (DDA) mode. Although, this helps to maximize amount of information obtained from an experiment, it has certain inherent limitations such as scan speed (Wenner and Lynn, 2004), selection of ion for further fragmentation, poor reproducibility, narrow dynamic range etc. (Law and Lim, 2013). Due to biases towards certain most intense fragments, DDA method has limitation of not being able to detect low abundant ion fragments. Targeted MS-based proteomics was developed to overcome these limitations of DDA mode. Targeted MS approach on Data independent mode (DIA) is dependent on a known reference spectrum, where identification could be performed from selected few fragment ion, rather than all possible fragment in DDA mode (Gillette and Carr, 2013). Success of data independent quantification relies on proper selection of distinct precursor ion-transitions (Tang et al., 2014). Hence, DDA mode is employed to filter top performing precursor-ions as inclusion list for DIA mode, so the MS instrument could select those specific fragments to aid in identification of low abundant ions/spectra.

Sequential Window Acquisition of all THEoretical fragment ion spectra coupled to Tandem Mass Spectrometry (SWATH-MS) is a novel identification/quantification methodology that operates in DIA mode in a label-free context. SWATH-MS, currently takes into account the peptides of mass/charge (m/z) range from 400 to 1200 and generates fragment ion spectra of all the precursor peptides falling within the window width of 25 Da in each cycle. A prerequisite assay library of peptides/proteins of interest, created in shotgun or discovery mode is required to identify and translate the detailed fragment ion spectral data which is produced in DIA mode and extracted through targeted data extraction approach (Vidova and Spacil, 2017). While performing the data analysis, a number of parameters are usually taken into consideration to perform efficient and high-confidence data analysis. These parameters are, precursor and product ion mass/charge values, retention times, generated spectra and relative intensities. Scores are calculated against peak groups and statistical validation is performed (see Fig. 2).

In this article, label-free relative quantification analysis using computational tools have been discussed and demonstrated on DIA data. Quantification data setup and pre-requisite steps to extract the useful information and measurements from experimental data have been illustrated in detail. Moreover, statistical analysis has been carried out on quantified experimental data to analyze proteome expression.

Data Analysis Software

The data independent acquisition strategy has led to the development of a number of specialized software and packages which implement high-speed accurate DIA analysis, from chromatogram extraction to quantification. Currently, in addition to the generalized data analysis packages, mass spectrometry vendors also encompass built-in software responsible for not only

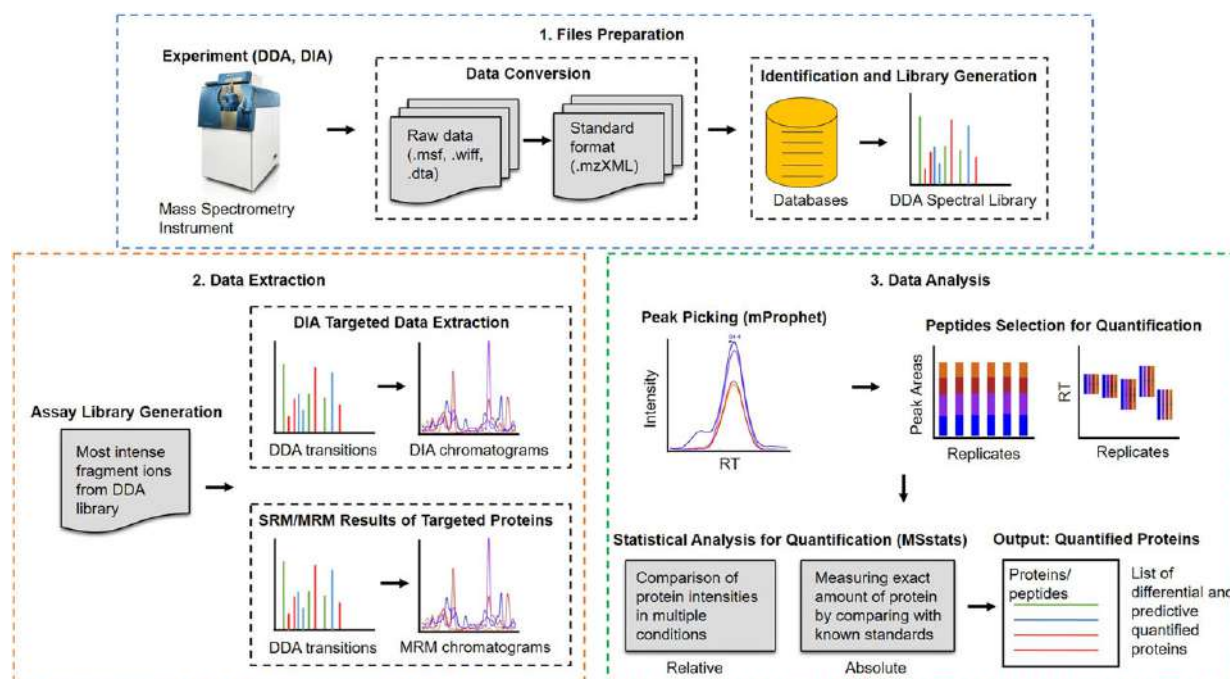

Fig. 2 Workflow of mass spectrometry based protein quantification. Data generated either in DIA or DDA (for the library) mode from a TOF or Orbitrap instrument are first converted to suitable standards followed by library generation from DDA data. Peaks are then extracted and picked for quantification. Finally, statistical analysis is performed to identify a list of differentially quantified proteins.

Table 1 Commonly used DIA (Data Independent Acquisition) data analysis software packages

Software	Enterprise	Specifications	Versions	Download link
PeakView	AB Sciex	● Commercial ● Windows-based ● Bio Tool Kit	V 1.1 (2010–2011) V 2.2 (2014)	https://sciex.com/products/software/peakview-software
OpenSWATH (Rost <i>et al.</i> , 2014)	OpenMS	● Free – Open Source ● Windows, Linux, Mac-based ● Compatible with AB Sciex, Thermo and Water DIA data	V 2.2.0 (2017) V 2.1.0 (2016)	https://github.com/OpenMS/OpenMS/releases
Skyline (Pino <i>et al.</i> , 2017)	MacCoss lab	● Free ● Windows-based ● Panorama repository	12 versions V 3.3 (2017)	https://skyline.ms/project/home/software/Skyline/begin.view
Spectronaut (Bruderer <i>et al.</i> , 2017)	Biognosys	● Commercial ● Windows-based ● Quantification of 1000 proteins from a single run	5 versions V 10.0 – Orion (latest)	https://biognosys.com/shop/spectronaut
DIA-Umpire (Tsou <i>et al.</i> , 2015)	Alexey Nesvizhskii lab	● Free – Open Source ● Untargeted, library-free peptide identification from DIA data	V 1.4 (2015) V 2.0 (2016) V 2.1 (2016)	http://diaumpire.sourceforge.net/

monitoring the MS experiment but also performing all the downstream data analysis. Some of the widely used software for DIA data analysis are presented in [Table 1](#).

Sample Dataset

The sample data was collected for the detection and quantification studies of yeast (*Saccharomyces cerevisiae*) proteome (Selevsek *et al.*, 2015). In this study, changes in yeast proteome expression have been analyzed in the presence of osmotic stress, progressively at different times. As stated above, DIA data analysis requires initial DDA runs to generate the library of assays. It is preferred to run the shotgun injections on the same instrument type as the final DIA data, however, the library assays can be transferred to different instrument platforms if similar fragmentation and chromatography techniques are adopted. In the current example, shotgun and DIA runs were performed on a 5600 TripleTof mass spectrometer (ABSciex) with NanoLC-2Dplus HPLC system. The instrument setup, parameters, collision energy and window settings are available in the study (Selevsek *et al.*, 2015). Additionally, all the data files were submitted to the ProteomeXchange repository (PRIDE) (ID: PXD001010) (see “Relevant Websites section”). These data files include DDA and DIA .wiff files which can be accessed and utilized for performing the quantitative analysis.

Computational Tools

For this article, to perform the identification and quantification of yeast proteome using DIA strategy, a number of tools were employed. For instance, DDA data was identified using TPP (Deutsch *et al.*, 2015). The identified spectra were converted into spectral libraries using SpectraST (Lam *et al.*, 2007) and Skyline. Targeted data extraction was performed in Skyline (Pino *et al.*, 2017). Peak scoring and statistical analysis were executed in Skyline using mProphet algorithm (Reiter *et al.*, 2011). Lastly, protein level relative quantification and significance analysis were carried out using MSstats functionalities (Choi *et al.*, 2014), supported in Skyline. Skyline software (see [Fig. 3](#)) can be freely downloaded, with mProphet and MSstats modules incorporated in Skyline.

Step1: Spectral Identification and Library Generation

The DDA-based library was generated by running shotgun experiments, comprising of 46 MS injections. These include samples from BY4741 strain and at different time points in response to osmotic shock. Details of these 46 injections are provided in the study (Selevsek *et al.*, 2015). The 46 data files are available online in wiff format with the following names:

1. ‘nselevse_L120203_006.wiff’ to ‘nselevse_L120203_029.wiff’ (24 files);
2. ‘nselevse_L120327_001.wiff’ to ‘nselevse_L120327_018.wiff’ (18 files);
3. ‘igillet_L120122_001.wiff’ to ‘igillet_L120122_003.wiff’ (3 files), and
4. ‘igillet_L120124_003.wiff’ (1 file).

The generated spectra were identified using TPP tools against *Saccharomyces* Genome Database (SGD) (Cherry *et al.*, 2012). The search results were statistically sorted according to probability at 1% FDR. The identified spectra from all the samples were then compiled to generate ‘iProphet_Combined.pepXML’ file and used to build a consensus spectral library.

Fig. 3 Skyline software start-up page.

Fig. 4 Library settings in Skyline for generation of spectral library.

Building a spectral library requires the following files:

- pepXML file (search engine result)
- mzXML files (spectral data)

The pepXML file is available at ProteomeXchange repository (ID: PXD001010) whereas mzXML spectra files can be acquired by converting 46 DDA wiff files to XML format using Msconvert tool (Kessner *et al.*, 2008). These converted mzXML data files are necessary to extract the chromatograms from the spectral library during DIA targeted data extraction.

Spectral library using Skyline

Skyline has a 'Build Library' module in 'Peptide Settings' to generate the spectral library (see Fig. 4). It requires library name as 'Yeast_Library.blib', output path and PeptideProphet cut-off score as '0.9' (false discovery rate of below 1%). Retention times, mass to charge values and relative intensity values for each spectrum are also stored in the spectral library, which can be visualized in the Skyline (see Fig. 5).

Step 2: Fragment Ion Library or Assay Library

Fragment ion library or assay library is a subset of the spectral library. It contains the most intense particular precursor and product ions (MS/MS transitions) from the spectral library or a targeted proteins list. These assays contribute in DIA targeted data extraction of peptides and proteins of interest. These characteristics have to be determined prior to importing the DIA data into the Skyline. For this purpose, Skyline provides various peptide and transition settings with 'Filter', 'Library' and 'Modifications' modules. 'Modification' allows one to include and exclude different types of structural and isotopic modifications. In addition to the default options, new

Fig. 5 Spectral library visualization in Skyline.

Fig. 6 Filter settings for transition selection in Skyline. (A) Peptide settings. (B) Transition settings.

modifications can also be added to the Skyline. In 'Filter' module, peptides length, precursor/product ion charges and types, and a number of ions can be determined (see Fig. 6). Subsequently, through 'Library' settings, ion match tolerance values (match between DIA and DDA data) and library to be added in the analysis can be set. It also provides options for selecting most intense transitions from the library, which also fulfils the 'Filter' settings (see Fig. 7). For the current data set, following criteria were set (see Figs. 6 and 7):

- Peptide length = min 8 and max 25
- Structural modifications = no oxidation on methionine

Fig. 7 Library settings for transition selection in Skyline. (A) Peptide settings. (B) Transition settings.

- Ion Intensities=highly intense in spectral library
- Ion Charges (precursor and product ions)=single (1) and double (2)
- Ion types=b, y and p (precursor) ions
- Precursor m/z exclusion window=5 m/z
- Match tolerance=0.05 m/z
- Number of selected transitions=top four

Using 'precursor m/z exclusion window' option, spectra in a mass window around precursor m/z value can be excluded to minimize the noise and extract the refined transitions. In the 'Library' and 'Filter' settings, further transition options are also given such as, 'auto-select all matching transitions', 'pick most intense transitions from library spectrum' and 'pick peptides matching both the library and filter settings'. After setting up the environment for transitions selection, a list of targeted proteins is loaded into the Skyline to generate the fragment or assay library.

Step 3: Targeted Proteins

In contrast to MRM data analysis, where proteins of interest are already determined prior to performing the experiment, in DIA, the list of targeted proteins or peptides are loaded after the experiment has been performed. This allows the extraction and analysis of DIA data that is only related to proteins of interest from the whole data independent run, which usually analyses all the peptides within the range of 400–1200 m/z (depending upon the instrument settings). The targeted proteins/peptides list can be provided in different ways in Skyline, such as, selected externally and imported into the skyline using 'Import Fasta' module, and/or adding all those proteins/peptides which are available in the spectral library. It can also be added by simply inserting the proteins and peptide sequences in 'Targets' module. In this study, peptides which were identified and stored in the spectral library, and external protein data i.e. 'Yeast.fasta' were added to the target list. The proteins present in the fasta file also undergo *in silico* tryptic digestion in Skyline. While the protein data is provided, all those transitions which matched the transition settings (in step 2) were added to the target list along with their abundances and retention time values, as shown in Fig. 8.

Step 4: DIA Data Extraction Environment

Before importing and extracting the DIA data from experimental runs, Skyline needs to set up the DIA environment. In this, all the instrument and isolation settings for MS1 and MS/MS filtering are configured in 'Transition Settings' under 'Full-Scan' module. The full-scan features include:

- Precursor mass analyzer
- Product mass analyzer
- Resolving powers of analyzers

Fig. 8 Visualization of targeted transitions list in Skyline.

- Acquisition method
- Isolation Scheme (pattern of precursor isolation windows in DIA acquisition)
- Retention time filtering

A DIA isolation scheme defines the pattern for each acquisition window (m/z range) through the entire mass range by the specific instrument. Skyline provides default isolation schemes with a variety of patterns, for example, SWATH (15 m/z), SWATH (25 m/z) etc. A customized pattern can also be designed and added according to the particular instrument used for data acquisition experiment. To set up a user-specific isolation scheme, following parameters are required:

- Mass range=400 to 1200 m/z
- Window (isolation) width=25 m/z
- Number of windows=32
- Total cycle time=3.3 s
- Accumulation time (time spent on single transition)=10 ms

For the current data set, these values are filled up according to the 5600 TripleTof mass spectrometer used for yeast proteome quantification, provided in the study (Selevsek *et al.*, 2015). After specifying the settings, Skyline displays the isolation windows in tabular and graphical form.

Retention time filtering defines the time range over which each chromatogram is extracted from DIA data against a single targeted transition. The chromatogram can be extracted over the entire gradient, however, it may result in the noisy and distorted peaks with a minimum understanding of correct chromatogram peak. For precise data extraction and identification, retention time value for each peptide in the experiment is required. Skyline provides couple of options limiting the RT range, such as, (i) using RT values of peptides found in the spectral library, (through DDA runs), (ii) predicting these values using SSRCalc hydrophobicity algorithm (Spicer *et al.*, 2007) and (iii) calculating RT values using standard RT peptides through empirical measurements (also called as normalized RTs or iRTs). Details of the SSRCalc and normalized RTs is available in the Skyline tutorial.

Subsequently, assigning the values to the other parameters in 'Full-Scan' module, set up the DIA and DDA environment in Skyline for data extraction and analysis (see Fig. 9).

- Precursor mass analyzer=TOF
- Product mass analyzer=TOF
- Resolving powers of analyzers=30,000
- Acquisition method=DIA

The screenshot shows the 'Transition Settings' dialog box in Skyline. It has five tabs: Prediction, Filter, Library, Instrument, and Full-Scan. The 'Filter' tab is selected. Inside the 'Filter' tab, there are two main sections: 'MS1 filtering' and 'MS/MS filtering'.
 In the 'MS1 filtering' section:
 - 'Isotope peaks included:' is set to 'Count'.
 - 'Precursor mass analyzer:' is set to 'TOF'.
 - 'Peaks:' is set to '3'.
 - 'Resolving power:' is set to '30,000'.
 - 'Isotope labeling enrichment:' is set to 'Default'.
 In the 'MS/MS filtering' section:
 - 'Acquisition method:' is set to 'DIA'.
 - 'Product mass analyzer:' is set to 'TOF'.
 - 'Isolation scheme:' is set to 'Yeast_Scheme'.
 - 'Resolving power:' is set to '30,000'.
 Below these sections, there is a checkbox 'Use high-selectivity extraction' which is unchecked.
 At the bottom, there is a 'Retention time filtering' section with three radio button options:
 - 'Use only scans within 5 minutes of MS/MS IDs' (selected).
 - 'Use only scans within 5 minutes of predicted RT'.
 - 'Include all matching scans'.
 At the very bottom are 'OK' and 'Cancel' buttons.

Fig. 9 MS1 and MS/MS filtering settings for DIA data extraction in Skyline.

- Isolation Scheme (pattern of precursor isolation windows in DIA acquisition)=Yeast_Scheme (user-defined)
- Retention time filtering=scans within 5 min of MS/MS IDs

This retention time filtering value will extract the chromatograms from DIA spectra within 5 min range of the peptide-spectrum match for each targeted peptide from the DDA run in a spectral library.

Step 5: DIA Targeted Data Extraction

Following setting up the environment in Skyline, data files from SWATH-MS runs for yeast biological replicates can be imported. In this study, changes in the *S. cerevisiae* proteome were quantified over 6-time points i.e. 0 min (T0), 15 min (T1), 30 min (T2), 60 min (T3), 90 min (T4) and 120 min (T5), as a result of osmolarity stress. Samples were collected, digested and analyzed using SWATH-MS in triplicates at each time point. The 18 data files are available on ProteomeXchange database (see “Relevant Websites section”) in wiff format with following names:

1. 'L120412_001_SW.wiff' to 'L120412_003_SW.wiff' (T0) (3 files);
2. 'L120412_004_SW.wiff' to 'L120412_006_SW.wiff' (T1) (3 files);
3. 'L120412_007_SW.wiff' to 'L120412_009_SW.wiff' (T2) (3 files);
4. 'L120412_010_SW.wiff' to 'L120412_012_SW.wiff' (T3) (3 files);
5. 'L120412_013_SW.wiff' to 'L120412_015_SW.wiff' (T4) (3 files); and
6. 'L120412_016_SW.wiff' to 'L120412_018_SW.wiff' (T5) (3 files).

These files can be imported directly into Skyline (compatible with different file formats) using 'Import Results' option in 'File' menu. 'Import Results' provides multiple preferences including (i) add single-injection replicates in files, (ii) add multi-injection replicates in directories, (iii) add one new replicate for different types of results (see Fig. 10). As the SWATH runs were added to the Skyline for analysis, it extracted the chromatograms against peptides available in the 'Targets' list while taking into account the retention time filtering parameter. This is also called as 'Targeted Data Extraction'.

Fig. 10 Import results module for importing mass spectrometry results in Skyline.

Peak picking and scoring

The extracted chromatograms then undergo the process of identifying the correct peak for each targeted peptide, which correlates best with the spectrum in the spectral library. Although this is done automatically, peaks can also be picked manually. For each match, matching scores are allocated, also called as 'dot products'. In order to select the best peak, in addition to its conventional heuristic method, Skyline has also incorporated mProphet algorithm (Reiter *et al.*, 2011) scoring strategy for measuring the similarity between chromatogram and library peaks to choose the best match. The mProphet algorithm takes into account various parameters for scoring purposes, such as:

- Co-elution
- Mass accuracy
- Peak shape
- Ion intensity
- Relative product ion abundance correlation
- Predicted retention time

Additionally, Skyline is equipped with the facility of training and customizing the mProphet peak picking and scoring model for peak determination. This can be executed by generating decoy peptides and calculating FDRs for peaks selection. Details of manual peak-spectrum matching are available in further readings.

Step 6: DIA Data Exploration and Analysis

After importing the DIA data and performing peak selection, chromatograms for 18 biological replicates can be visualized, simultaneously. This can be done by arranging result files systematically into three groups in tabular form using 'Arrange Graphs' module of the Skyline in 'View' menu. Each group indicates the data for all six time points in each replicate. Chromatograms for the first replicate at time T0 to T5 are displayed in Fig. 11. In each graph, best peaks are displayed within the black dotted lines

Fig. 11 Chromatograms of yeast peptide from DIA data in replicate 1 at six time points. (A) 0 min (T0). (B) 15 min (T1). (C) 30 min (T2). (D) 60 min (T3). (E) 90 min (T4). (F) 120 min (T5).

which indicates the peak boundaries. Visualization and graphical attributes of chromatograms can be customized using a variety of options in 'View' menu, such as:

- Retention times (all or best peak)=Best peak
- Peptide ID times (none or matching with library)=Matching
- Transitions (all, precursor or products)=All
- Transform (interpolated or Savitsky-Golay smoothing)=Savitzky-Golay Smoothing
- Auto-zoom X-axis=Best peak
- Auto-scale Y-axis

Peptides selection for quantification

From the given list of targeted proteins, a number of peptides or peaks are matched and identified (from DIA and DDA data). For the downstream quantification measurements, those peptides should be incorporated in a way that shows consistency in their peak areas and retention times in multiple replicates. So, in order to perform this refinement, peak intensities and RTs of all the peptides can be compared and inspected using Skyline. In 'View' menu, 'Replicate Comparison' option for 'Retention Times' and 'Peak Areas' can be used to analyze the intensity and time comparisons in all 18 DIA replicate runs for yeast proteome at six time points.

In retention time replicate view (see Fig. 12(A)), following graph parameters were set:

- Value (all or retention time)=All
- Transitions (all, precursor or product ions)=All
- Order (acquired time or document)=Document

The RT of each fragment ion is represented in separate color and collectively each set of bars indicates the RT pattern of the whole peptide, over 18 runs. The start and end retention time points depict the elution times of the peptide in triplicates. The same height of all the groups shows that the peptide elutes in approximately equal time at all six time points.

In peak intensity replicate view (see Fig. 12(B)), following graph parameters were set:

- Normalized to (total, maximize or none)=None
- Transitions (all, precursor or product ions)=All
- Order (acquired time or document)=Document

The intensity of each fragment ion is illustrated in different colors and collectively each bar indicates the peak intensity of the whole peptide, over 18 runs. From the graph, it can be demonstrated that intensity values get lower after 15 min of exposure to osmotic stress in replicate 1 and 3, whereas, a slight increase in intensity is observed at 90 min and 120 min of exposure. However, in replicate 2, the intensity values during first 60 min are approximately the same and get decreased at 90 and 120 min. Moreover, relative transition intensity of peptides in all 18 runs can be visualized by normalizing the values to 'Total' in 'Peak Area' option in the replicate graph.

Consequently, similar peak intensity and retention time pattern among all the replicates validate the reproducibility of the MS instrument and experiment. It also depicts that the Skyline has identified and picked the correct peak for that particular peptide. Similarly, all the peptides can be inspected through these graphs individually from the target list, to select for quantification purposes.

If the intensity and retention time data for a peptide is not consistent among replicates (see Fig. 13), it can be improved by manual selection of correct peaks. It can be observed in Fig. 14 that for this particular peptide, unlike replicate 3, the correct peak is not selected in replicate 1 and replicate 2. This can be resolved by moving the peak boundaries via dragging the black dotted lines

Fig. 12 Consistent replicate comparison graphs in Skyline. (A) Retention times (B) Peak areas.

Fig. 13 Inconsistent replicate comparison graphs in Skyline. (A) Retention times (B) Peak areas.

Fig. 14 Chromatograms of selected peaks at 15 min in Skyline. Incorrect peaks are selected in (A) Replicate 1 and (B) Replicate 2. (C) Peak in Replicate 3 is correctly identified.

Fig. 15 Chromatograms of correctly selected peaks for specific peptide at 15 min. (A) Replicate 1. (B) Replicate 2. (C) Retention times consistency. (D) Peak areas consistency.

around the peaks. These corrections can now be observed in peak area and retention time graphs as well (see Fig. 15). If the data does not show consistency even after adjustments, the insignificant peptide can be deleted from the study.

Step 7: Statistical Analysis for Quantification

The aim of this study was to quantify the abundance of yeast proteome in response to the osmotic stress condition and identify those proteins which show a significant change over the course of the time period of two hours. Skyline provides the facility of performing this statistical analysis by annotating the replicate data with some additional classes or conditions. In this case study, conditions are the different time points, along which we have to observe the changes. Data annotation can be performed using 'Define Annotation' module in the 'Document Settings' in Skyline. Condition values are named as 'a0m', 'b15m', 'c30m', 'd60m', 'e90m' and 'f120m' and applied onto 'Replicates' (see Fig. 16). Select 'Condition' and 'BioReplicate' in 'Document Settings' to incorporate these annotations into the current Skyline document to analyze yeast data.

Intensity and time variation among technical replicates

Using replicate comparison function of Skyline, variation among the intensities and retention times of the quantotypic peptides in different conditions can be analyzed. In peak areas and retention time views, following graph parameters were set:

- Transitions (all, precursor, products or total)=Total
- Group by (replicate or condition)=Condition
- Normalized to (maximum, total or none)=Maximize
- Select CV values

Graphs shown in Fig. 17 illustrate the variation among different conditions or time points for this particular peptide belonging to protein 'YGR240C', in all replicates. All the peptides can be analyzed by iterating over the entire set of targeted proteins. It can be deduced from the graph (see Fig. 17) that intensity of this specific peptide greatly varies among all replicates at 90 min after the exposure to osmotic stress environment and the least variation is observed at 0 min and 120 min.

Fig. 16 Annotation module for defining new annotations for replicate data in Skyline.

Fig. 17 Variation among replicates at six time points. (A) Intensity. (B) Time.

Average peptide abundance among conditions

To study the average peptide abundance or difference in peptide expression among different conditions, following graph parameters were set in peak areas replicate comparison view:

- Transitions (all, precursor, products or total)=Total
- Group by (replicate or condition)=Condition
- Normalized to (maximum, total or none)=Total
- Deselect CV values

The graph in [Fig. 18](#) presents the average mean of peptide abundances in triplicates among all conditions. The red bars in the graph represent the mean average values and black lines on the bars represent the standard deviation, which measures the amount of dispersion in the intensity values. A high standard deviation at 90 min depicts the high variation in data values at this time in all replicates.

Overlapping mean values for this specific peptide at six time points, shown in the [Figs. 17](#) and [18](#), do not contribute greatly to the differential abundance analysis, and therefore, demonstrate that protein 'YGR240C' exhibits no significant response to osmotic stress. Contrary to this, peptide response from protein 'YMR169C', shown in [Fig. 19](#), is highly predictive and presents a supposition

Fig. 18 Average peptide abundances among replicates at six time points.

Fig. 19 Significant change in abundances during six time points after osmotic shock.

that this protein may have been upregulated under the influence of osmotic stress. However, this hypothesis requires the similar behaviour from more than one peptide to validate the up or down-regulation of the corresponding protein.

Group comparison among conditions

Differential abundance analysis between time points can also be performed through pairwise group comparison investigation i.e. measure the change in abundance between time points:

- 0 min (T0) to 15 min (T1)
- 0 min (T0) to 30 min (T2)
- 0 min (T0) to 60 min (T3)
- 0 min (T0) to 90 min (T4)
- 0 min (T0) to 120 min (T5)

In Skyline, 'Group Comparison' module in 'Document Settings' provides the facility of adding as many comparisons as required. In 'Edit Group Comparison' form, for the first comparison, following parameters were set:

- Name=T0 v. T1
- Control group annotation=Condition
- Control group value=a0m

Fig. 20 Log2 fold change in abundances of proteins during the time period between 0 min (T0) and 15 min (T1).

- Value to compare against=b15m
- Identity annotation=BioReplicate
- Normalization method=Equalize medians
- Confidence level=95%
- Scope=Peptide or Protein for peptide or protein level analysis, respectively

To inspect the abundances of proteins within the time frame of first 15 min, the graph can be visualized in 'View' and 'Group Comparison' menu of Skyline. The graph shown in [Fig. 20](#) illustrates the overall fold change, either increase or decrease or no effect, in yeast proteins. By employing the same method on all other comparison groups, protein expressions during different time periods can be analyzed.

Data Visualization

Different quantification strategies provide a measure of change in proteome between different biological conditions/samples. Elucidation of biological relevancy of these quantifications requires additional analysis. Perseus is widely adopted for analysis post-database search, for visualization and statistical analysis. There are various tools available for pathway enrichment and analysis, Gene ontology (GO) enrichment could be performed by Panther ([Mi et al., 2016](#)), protein-protein interaction information could be obtained from STRING ([Szklarczyk et al., 2015](#)), IntAct ([Orchard et al., 2014](#)), Human Protein Reference Database (HPRD) ([Keshava Prasad et al., 2009](#)) and Biological General Repository for Interaction Datasets (BioGRID) ([Stark et al., 2011](#)) amongst others.

Perseus ([Tyanova et al., 2016](#)) is a freely available software that performs shotgun proteomics analysis of biological relevance from processed raw files. In addition, can perform various visualization, clustering, principal component analysis (PCA) and statistical tests on quantitative and time series data, details of which are available on Perseus documentation.

Conclusion

Mass spectrometry based quantitative proteomics has rapidly changed the landscape of proteomics research spurred on by rapid technological advances and more importantly huge strides ahead in computational analysis and informatics. It has to be noted though, that the major limitation of quantitative studies is the thresholds and stringencies set by the users. Although there is yet to be standards developed for quantitative proteomics ([Mohamedali et al., 2017](#)), it behoves researchers and users to be wary of and thoroughly statistically analyze all mass spectrometry data keeping strict stringency to eliminate false positives. The example used in this article illustrates that the procedure for the analysis for protein quantification by proteomics is relatively straightforward with freely available tools. It has to be emphasised though, that users have a good understanding of the theoretical underpinnings of Mass Spectrometry and informatics to ensure that the results obtained from their studies are robust and reproducible.

Furthermore, upon the identification of differentially expressed proteins between samples after a rigorous experimental and analytical approach, orthogonal techniques to validate potential candidates using targeted techniques such as MRM's and ELISA are almost a compulsory part of the reliability of MS quantification ([Vidova and Spacil, 2017](#)). The use therefore, of large scale quantitative proteomics using a label-free DIA approach has been a mainstay of the discovery part of proteomic studies and indeed

has proven to be a formidable, robust and reliable method of quantifying large numbers of proteins in complex biological samples. Certain limitations such as the size and nature of libraries, quality of sample preparation, reproducibility on varied instruments, quality of data, statistical threshold guidelines etc. all still mean that quantitative proteomics has a way to go to achieve the robustness and reliability of quantitative transcriptomics.

Biographical Sketch

Zainab is a PhD student in the department of Chemistry and Biomolecular sciences (Bioinformatics group) at Macquarie University. She has been working in the area of protein structure and function analysis during her bachelors and masters' studies. Previously, she worked on identifying novel potent drug-like compounds against histone deacetylases proteins by employing *in silico* drug designing techniques. Currently, she is involved in programming-based mass spectrometry data analysis of data generated through data-dependent acquisition (DDA) and data-independent acquisition (DIA) approaches related to colorectal cancer. More specifically, she is dealing with the customization of DDA based spectral libraries to be used in DIA data analysis for biomarker discovery.

Subash is a PhD student in Cancer proteomics. His main interest is on mass spectrometry based quantitative proteomics. He is currently working on peptide antagonist against specific membrane protein-protein interaction that are known to drive epithelial cancer metastasis.

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books as well as contributed several articles to Springer's Encyclopedia of Systems Biology. She is currently the Editor-in-Chief of Elsevier's Encyclopedia of Bioinformatics and Computational Biology as well as the Bioinformatics Section Editor for Elsevier's Reference Module in Life Sciences.

Abidali is a Lecturer at Macquarie University in the Faculty of Science and Engineering. He completed his PhD in 2010 studying, using proteomics, the effects of single mutations in mouse model on brain development in the autism spectrum disorder, Rett syndrome. He then returned to Macquarie University undertaking a post-doc to study the biology of metastasis in colorectal cancer using quantitative proteomics and to determine novel therapeutic targets and develop novel technologies to examine the plasma proteome.

Introduction

Living cells and tissues exist in a state of constant flux, responding to, and acting upon, a complex matrix of biochemical signals and genetic programming in order to maintain and perpetuate life. As such, cells and tissues can be considered fluidic in terms of stimulus and response rather than remaining static. Though DNA encodes the foundational 'blueprint' for life, it is the shifting creation or destruction of its downstream effectors (RNAs, proteins and their modifications) that carry out the functionality of the ~20,300 protein-coding genes. The study of these shifts in the protein population as a result of disease, cancer, lifestyle, aging or response to treatment is known as proteomic analysis (or proteomics); which refers to the systematic identification and quantitation of the complete complement of proteins (the proteome) within a biological system at a specific point in time (see Relevant Websites section). Therefore, by establishing specific time points or suitable models of comparison, proteomic analysis can be applied to investigations of biological fluids, cells, tissues, organs or organisms as a means to assess the shifts in protein expression that accompany disease states such as cancer or as a means to identify specific markers of disease (biomarkers).

Thus, proteomics is a method for identifying the change in protein populations that correlate with the presence or progression of a disease. Though it can be applied to the tissue and whole-organism level for microbiota, its strength lies in its capacity to identify cellular behaviour, making it a well-adopted method to explore the cellular biology of cancer. One of the most studied yet still poorly understood diseases, cancer originates from a single malignantly-transformed cell in a multi-staged process that confers a growth advantage compared to the surrounding healthy cells (see Relevant Websites section) (Uhlen *et al.*, 2015). The transformation of a 'healthy' somatic cell into a cancerous lesion is not the result of a single mutation but rather the interplay between large numbers of genes with diverse normal functions. More than 500 genes have been implicated in the transformational process. Whilst these genes and their protein products are necessary for normal growth, survival and function, dysregulation of their expression is what drives or enables a cell to escape healthy cell programming and become cancerous. Dysregulation of normal expression can occur as either a result of overexpression, reduced expression (downregulation) or the expression of a defect protein, each of which can contribute to unregulated tumour growth. To grasp the scale of global morbidity, cancer killed 8.2 million people in 2012 as a result of unregulated cell growth that led to eventual metastasis, multiple organ failure and death (Ferlay *et al.*, 2015). A given cancer can be classified as one of several diseases based upon the organ of origin (i.e., where the primary cancer developed), tumour morphology or molecular features. Along with stage at the time of diagnosis, each of these factors form important determinants for the clinical outcome and choice of treatment for the patient.

Proteomic profiling is one of the several means to characterise a cancerous cell or tissue, providing information on the protein population within that sample and revealing a valuable insight into the biology of a given tumour. Proteomic profiling also facilitates detailed comparison between tumours and their corresponding tissue of origin, providing researchers and clinicians with the differential expression of biologically-relevant proteins between individual tumours or between different types of cancer. Proteomic profiling can also be employed to examine differential protein expression between regions of a given tumour, or of tumour cells at different cancer stages. The key task of these investigations is to identify proteins that are functionally relevant to the progression of the disease, such as markers of cancer stage, aggression and indicators of response to therapy. However, one of the primary difficulties faced by these studies is that these biologically-relevant proteins are found in very low abundance (or copy-number) relative to the vast numbers of somatic 'house-keeping' proteins. More specifically, the dynamic range of protein

Fig. 1 Schematic representation of proteins identified and quantified within the observable proteome. Cellular proteins span a wide range of copy numbers, with only a fraction of the total being able to be identified, of which only a small percentage can be quantified using currently available molecular biology and mass spectrometry techniques. Biomarkers and pathologically important proteins are often found in very low abundance which makes it challenging to identify and quantify them. Figure modified from Bantscheff, M., Schirle, M., Sweetman, G., Rick, J., Kuster, B., 2007. Quantitative mass spectrometry in proteomics: A critical review. *Anal Bioanal Chem* 389, 1017–1031.

populations in a sample can span several orders of magnitude. The issue of dynamic range between proteins of interest and the somatic population is a constant challenge to the analysis of a range of specimen types such as cell lysates, tissue lysates or plasma. For example, clinical tissue sections contain highly abundant blood-derived proteins that originate from the tissue-embedded network of blood/lymph capillaries and interstitial fluid (Prieto *et al.*, 2014), whilst in biofluids such as plasma, the 22 most-abundant proteins constitute 99% of the total plasma protein mass (Fig. 1) (Prieto *et al.*, 2014; Bantscheff *et al.*, 2007).

As a result, investigations require the use of effective separation techniques to delve deeper into the proteome to identify proteins and peptides that are relevant to a given disease state. The field of proteomics has developed an extensive toolbox of methods that can be applied to such a problem, employing mass spectrometry (MS) as the principal technique for the identification of proteins (and their associated pathways) that are differentially-expressed as a result of carcinogenesis, progression or metastasis. MS enables researchers and clinicians to identify the specific mass and charge state of amino acid sequences which can be matched *in silico* to a peptide sequence and thus identify the parent protein from which the peptide was derived. This process is known as peptide-to-spectra matching. However, the complexity of biological samples can result in the masking of proteins of interest amongst the much more abundant house-keeping proteins. Therefore, reducing sample complexity or enriching for a protein subpopulation of interest is a critical component of the proteomic workflow, which can be achieved by methods such as mass-, charge- or hydrophobicity-based fractionation, subcellular or affinity-based fractionation (Table 1). These methods can be employed either individually or in combination at both the peptide and protein levels.

Once sample complexity has been reduced, multiple proteomic strategies may be used to identify the complement of proteins within. A hierarchical structure of the some commonly used workflows by biomedical researchers is illustrated in Fig. 2. These techniques and workflows are chosen on the basis of the experimental design and include methods such as: label-free and labelled proteomics, gel-based and gel-free proteomics. Each method possesses respective strengths and weaknesses which must be factored into a proposed experimental design.

One method that enables researchers to reduce sample complexity without relying upon mass-based separation is immobilised pH gradient isoelectric focussing (IPG-IEF), which enables separation based on isoelectric point (pI). This method addresses a problem with direct injection of a sample onto an LC-MS/MS system, which is that a single-dimension separation by reversed-phase LC and does not afford a sufficient peak capacity to successfully process all of the tens of thousands of peptide species that are present within an unfractionated tryptic digest of a complex biological sample. More specifically, IPG-IEF employs an immobilised pH gradient within an acrylamide matrix by integrating acrylamide buffer molecules during gel casting. As a result, when placed under a current, the peptides or proteins that are loaded onto the gel strip will migrate along the one-dimensional gel until they reach their respective isoelectric points, where they will cease to migrate. Once the run is complete, the gel strip can be fractionated by excising sections of the gel, eluting the peptides into solution followed by further separation by the front-end liquid chromatography prior to in-line MS (Pergande and Cologna, 2017; Liu *et al.*, 2016).

As mentioned previously, MS is most often applied for analysis of proteins in a single cell or an organism. Once sample complexity has been reduced using the protein/peptide separation techniques outlined in Table 1, low abundance proteins peptides/proteins can be identified by label-free or labelled proteomic approaches. The respective advantages and disadvantages of these methods are outlined in Table 2.

These respective strengths and weaknesses must be considered as current proteomic methods still only identify a small percentage of the total proteome (as shown in Fig. 1) (Bantscheff *et al.*, 2007). Furthermore, proteomic investigations must also

Table 1 A comparison of protein/peptide fractionation or enrichment methods that are commonly employed in proteomic workflows in order to reduce sample complexity

Fractionation/ enrichment procedure	Principle	Strengths	Weaknesses	Comments	Ref (s)
<i>Gel-based fractionation methods</i>					
1D SDS-PAGE	Separation based on protein charge and mass (i.e. protein size)	1. Applicable to a wide variety of samples 2. Simple to run 3. Fast turnaround	1. Requires fairly large amount of sample 2. High inter-gel variability 3. Multiplexing is not possible 4. Requires multiple runs for quantitation 5. Difficult to identify low-abundance and small proteins unless the sample has been enriched for those proteins 6. Proteins with similar masses cannot be resolved due to masking 7. Incomplete digestion may introduce error	This techniques is very widespread and used for many applications such as comparing the protein composition of different samples, analysis of the number and size of polypeptide subunits, western blotting coupled to immunodetection	Tiwari and Tiwari (2014), Abdallah <i>et al.</i> (2012)
IPG-IEF	Separation based on isoelectric point (pI) of peptides and/or proteins	1. High-resolution and high-capacity method for peptide separation 2. Full control of a well-defined pH range 3. Flexibility of choosing the desired pH gradient 4. Buffering capacity 5. Reproducible separation for technical replicates	1. Oil from IPG-IEF fractionation must be removed prior to MS 2. Additional sample-handling steps 3. Cathodic drift of proteins with alkaline pls 4. Poor resolution under non-denaturing conditions	Separation by net charge at different pH values is not affected by protein molecular weight	Moreda-Pineiro <i>et al.</i> (2014) Abdallah <i>et al.</i> (2012); Manadas <i>et al.</i> (2010), Essader <i>et al.</i> (2005)
2D SDS-PAGE or 2D-DIGE	Separation based on pI (first dimension separation) and then by protein size (second dimension separation)	1. Simplistic to run 2. Robust 3. Can be multiplexed using Cy-dyes	1. Requires large sample amounts 2. Low throughput 3. High inter-gel variability 4. Co-migration of multiple proteins in a single spot renders comparative quantification rather inaccurate 5. Poor representation of low abundant proteins 6. Has issues separating highly acidic/basic proteins, or proteins with extreme size or hydrophobicity		Tiwari and Tiwari (2014), Abdallah <i>et al.</i> (2012)

(Continued)

Table 1 Continued

Fractionation/ enrichment procedure	Principle	Strengths	Weaknesses	Comments	Ref (s)
<i>Salts/detergent based enrichment methods</i>					
Sodium Carbonate	High alkalinity of sodium carbonate solution (pH 11) solubilises and strips loosely associated proteins from cell membranes	1. Simple procedure 2. Inexpensive reagents 3. Avoid labelling 4. Extended proteomic coverage 5. Highly abundant cytosolic proteins (e.g., ribosomal proteins, elongation factors) are easily separated	1. Require large amount of samples 2. Only enriches loosely bound membrane proteins which sometimes is not ideal 3. Involves centrifugation at $120,000 \times g$, which many not be suitable for all membrane types		Cantor <i>et al.</i> (2013), Molloy (2008)
Triton X-114 Phase partitioning	Triton X-114 is used to solubilise the membrane proteins which are then separated (at 20°C) from hydrophilic proteins	1. Simple workflow 2. Hydrophobic and hydrophilic proteins are enriched 3. Ideal for analysis of membrane proteins 4. Inexpensive	1. More difficult sample preparation procedure 2. Require large amount of samples 3. Sample loss at each step 4. Requires detergent removal which would otherwise interfere with MS analysis	This method was first introduced by Bordier in 1981. It has now established itself as one of the most powerful tools for preparing membrane proteins for analysis	Mathias <i>et al.</i> (2011), Pryde (1998); Bordier (1981)
<i>Chromatographic fractionation methods</i>					
Ion Exchange chromatography	AX: Positive groups have affinity for negatively charged peptides at basic pH	1. Robust 2. Less labour intensive	1. Limited resolution	Strong cation exchange (SCX) is the most commonly used fractionation technique for proteomics. It has also extensively used to study post-translational modifications	Chan and Issaq (2013), Mohammed and Heck (2011) Manadas <i>et al.</i> (2010), Essader <i>et al.</i> (2005)
Anion exchange chromatography (AX)	CX: Negative groups attract positively charged peptides at acidic pH				
Cation exchange chromatography (CX)	Separation is based on the analyte partition coefficient between the polar mobile phase and the hydrophobic (nonpolar) stationary phase	1. Can provide extremely high resolution separations 2. Reverse phase columns are relatively cheap and commercially available 3. Easy to use	1. Very sensitive to polarity, changes in temperature and pH 2. These can have profound effects on the results		Abdallah <i>et al.</i> (2012)
Reverse phase chromatography					

OFFGEL electrophoresis	Separation is based on pI of peptides/proteins	1. Improved pI resolutions 2. Sample is recovered in liquid phase 3. Low influence of offgel reagents on further separation techniques 4. High reproducibility 5. Multiple samples can be fractionated in parallel	1. Requires high amount of sample 2. Possible loss of sample 3. Long separation-times (few hours to 2–4 days) 4. Moderate number of protein identifications 5. Cathodic drift of proteins with alkaline pls 6. Poor resolution under non-denaturing conditions	Moreda-Pineiro <i>et al.</i> (2014), Manadas <i>et al.</i> (2010) http://www.agilent.com
<i>Depletion columns for enrichment</i>				
Multiple Affinity Removal System (MARS)-14	Antibody based protein capture	1. Removes 14 high-abundance proteins from human plasma samples 2. Enhances the ability to identify low abundance proteins	1. Variable depletion efficiency between proteins 2. Concomitant loss of non-targeted proteins 3. High cost 4. Can only be used with serum/plasma	Ahn and Khan (2014), Tu <i>et al.</i> (2010) Pernemalm <i>et al.</i> (2008) http://www.agilent.com
ProteoPrep20 Plasma Immunodepletion Kit	Antibody based protein capture	1. Removes the 20 most-abundant proteins which allows for 50-fold increased protein loads 2. Increase the ability to visualize low abundance proteins and biomarkers 3. Convenient spin column format	1. Can only be used with biological fluids such as serum/plasma 2. Variable depletion efficiency 3. Concomitant loss of non-targeted proteins 4. High cost	Liu <i>et al.</i> (2011), Cellar <i>et al.</i> (2009), Sigdel and Sarwal (2008) http://www.sigmaldrich.com
HiTrap Albumin and IgG Depletion columns	Media containing recombinant Protein G fragments and recombinant protein binding human serum albumin (HAS)	1. Columns can be prepacked for either serum or plasma 2. Rapid and easy process 3. Large sample volumes (~150 µl) 4. Can be used online with an LC system or be used manually with a syringe 5. High depletion capacity, > 95% HSA and 90% IgG	14 proteins: Albumin, IgG, antitrypsin, IgA, transferrin, haptoglobin, fibrinogen, alpha2-macroglobulin, alpha1-acidglycoprotein, IgM, apolipoprotein AI, apolipoprotein AII, complement C3, transthyretin. 20 proteins: Albumin, IgG, transferrin, fibrinogen, IgA, alpha2-macroglobulin, IgM, alpha1-antitrypsin, complement C3, haptoglobin, apolipoprotein A1, A3 and B; alpha1-acid glycoprotein, ceruloplasmin, complement C4, C1q; IgD, prealbumin, and plasminogen Smaller columns can be purchased as Spin Trap from GE Healthcare	de Moraes-Zani <i>et al.</i> (2011) http://www.gelifesciences.com

Fig. 2 An overview of mass spectrometry-based proteomic workflows that are commonly employed by biomedical researchers. Figure adapted from Chandramouli, K., Qian, P.Y., 2009. Proteomics: Challenges, techniques and possibilities to overcome biological sample complexity. *Hum Genomics Proteomics* 2009. doi:10.4061/2009/239204.

account for the required use of combination/s of separation techniques in order to reduce sample complexity, especially during technical stages which may introduce experimental variation and downstream quantitative error (Fig. 3).

Stand-alone MS is not inherently quantitative due to ion loss and the sources of variation outlined in Fig. 3. As a result, labelling methods such as TMT, iTRAQ or SILAC, or multiple reaction monitoring (MRM) are often employed to enable researchers to accurately quantitate protein expression between samples or in reference to standards (Chan *et al.*, 2016). The key challenge encountered in MS-based biomarker discovery studies is the need for the greatest proteomic coverage that can be reliably and reproducibly achieved in order to identify and quantify the low abundance proteins whose altered expression may indicate or mediate disease (Chan *et al.*, 2016).

Table 2 Relative strengths and weaknesses of labelled and label-free proteomic strategies

	Advantages	Disadvantages
Label-free proteomic approach	● Requires less amounts of sample ● Higher proteomic coverage ● Avoid labelling ● Reagents are inexpensive ● Applicable to wide variety of samples ● Applicable to a wider variety of sample preparation workflows	● Multiplexing is not possible in one experiment ● Semi-quantitative, requiring multiple runs for quantitation ● Not suitable for low abundance proteins unless the sample has been enriched for those proteins ● Incomplete digestion may introduce error ● Technical variation must be tightly controlled
Labelled proteomic approach	● Faster MS analysis, requiring fewer runs. ● Applicable to wide variety of samples ● Allows multiplexing (3–10 samples) in a single in MS run, reducing technical variation between MS gradients. ● Allows better quantitation through the use of standards ● Minimises background by identifying tagged peptides only ● Covalent labelling can be achieved using iTRAQ and TMT ● Metabolic labelling can be performed using SILAC	● Requires greater amounts of sample ● Incomplete/partial labelling can introduce quantitative error ● Loss of the label causes peptide loss ● Reagents are expensive, therefore limiting the number of experiments that can be performed using a single sample

As a result, additional dimensions of sample separation are beneficial to biomarker discovery studies as they increase resolution and sensitivity of the shotgun proteomic workflow, whilst facilitating the application of a pI filter to reduce false positive or false negative PSMs (Cargile *et al.*, 2005). This article will explore the use of the gel-based and gel-free methods to identify differentially-expressed proteins, outlining their respective strengths and utility for vastly different proteomic applications, from the detection of performance enhancing drugs to elucidating the molecular biology of leading cancer subtypes.

Application of IPG-IEF

IPG-IEF is a robust protein/peptide fractionation technique that provides reproducible high resolution separation, (Moreda-Pineiro *et al.*, 2014; Abdallah *et al.*, 2012) and is therefore an attractive method to employ in biomarker studies where it is crucial to overcome the issue of sample heterogeneity. As a method of separation, IPG-IEF and its related methodologies have been a widely employed approach to fractionate protein mixtures prior to MS (Pergande and Cologna, 2017; Cargile *et al.*, 2005). One of the earliest incarnations of this approach was two-dimensional electrophoresis (2DE), in which IPG-IEF was applied as the first dimension of separation. The strength of 2DE over one-dimensional gels was the ability to separate and identify different proteoforms present within the sample. This additional dimension enabled early efforts to investigate, characterise and identify post-translational modifications (PTMs), the strengths of which have been reviewed by Westermeyer (2014).

However, early 2DE efforts were hamstrung by the inherent variations in gel composition and electrophoretic conditions, resulting in potentially significant gel-to-gel variation. Despite this issue, when employed in isolation, one of the greatest powers of 2DE and related IEF techniques was their complementarity with mass spectrometry. When used together, two-dimensional separation was able to reduce proteome complexity with sufficient resolution to facilitate the analysis of single proteoforms in greater depth compared to a standard shotgun approach (Pergande and Cologna, 2017). Furthermore, it is now common practice to perform 2DE with multiple Cy-dye labelled samples, thereby separating multiplexed protein samples under identical electrophoretic conditions and enabling researchers to visualise differential protein expression based on the size and location of protein spots. These gel spots are then easily excised and processed for MS analysis by either LC-MS or MALDI-TOF for *m/z*-based identification (Pergande and Cologna, 2017).

Additionally, the recent development of high-resolution isoelectric focusing (HiRIEF) by Branca *et al.* (2014) has allowed far deeper proteome coverage and the discovery of new protein-coding loci (Branca *et al.*, 2014). Using this specialised method, Branca *et al.*, were able to identify 77,985 human peptides, 39,941 of which had not been present in the human subset of the 2012 release of Peptide Atlas, corresponding to an increase of ~52% (Branca *et al.*, 2014). HiRIEF employs a series of ultra-narrow IPG gradients within the acidic pH 3.7–5.0 range (i.e., 3.70–4.05, 4.00–4.25, 4.20–4.45 and 4.39–4.99) which were then fractionated into 72 fractions for analysis by LC-MS/MS (Branca *et al.*, 2014). This method concentrated on the separation of acidic peptides as it enabled the identification of one third of the human tryptic peptidome. Furthermore, fractionation can be performed with minimal redundancy whilst remaining relatively robust in terms of resolution, the reduction in sample complexity and overall

Fig. 3 An overview of potential sources of variation and quantitative error within various proteomic workflows. Boxes displayed in green or yellow represent separate experimental conditions along a vertical workflow, with horizontal lines indicating stages where samples/data are combined. Paler boxes with dashed lines indicate technical stages that are susceptible to experimental variation. Covalent chemical labelling can be performed at either the protein or peptide level depending upon experimental workflow. Figure modified and adapted from Bantscheff, M., Schirle, M., Sweetman, G., Rick, J., Kuster, B., 2007. Quantitative mass spectrometry in proteomics: A critical review. *Anal Bioanal Chem* 389, 1017–1031.

reproducibility (Branca *et al.*, 2014). HiRIEF has more recently been applied to analyse sequential phosphorylation by protein kinases through the combined use of fluorescent peptide substrates with microfluidic isoelectric focusing and monitoring of protein folding dynamics (Pergande and Cologna, 2017).

IPG-IEF has been applied to investigate a great number of biological questions, some of which have been summarised in Table 3. These studies employed IPG-IEF and/or related methodologies in order to investigate an array of disease models, or to identify and/or elucidate the role of specific proteins as potential markers of disease. Here, we provide two case studies to highlight the application of IPG-IEF in biomedical research. In the first case study, IPG-IEF was used in combination with MARS depletion and iTRAQ to identify markers of the use of Human Growth Hormone in athletes as a performance enhancing drug; whilst in the second case study, IPG-IEF was paired with sample enrichment techniques to facilitate the identification of low-abundance and technically challenging proteins by LC-MS.

Case Studies

Case Study I

The first Case Study that we wish to explore is the recently published work by Tan *et al.* (2017). This study demonstrates the application of proteomic technologies to identify markers of substance abuse, specifically the administration of human growth hormone (GH) as a performance enhancing drug in competitive sports (Tan *et al.*, 2017). The World Anti-Doping Agency currently adopts two approaches for the detection of GH abuse in elite sports; the GH isoform test and GH biomarker test (Tan *et al.*, 2017). The GH biomarker tests measure the concentration of two human GH-sensitive markers which are present in serum; insulin-like

Table 3 A selection of IPG-IEF-based investigations that have been undertaken in the past 5 years

Author	Year	Disease/cancer type/ application	IPG-IEF utilisation	Key findings/notes	References
Tan SH <i>et al.</i>	2017	Testing of human growth hormone intake	MARS-7 depleted plasma samples were subjected to 2D-DIGE and selected spots were identified using MALDI-TOF MS	52 Spots from two phases were excised for MS analysis 20 Proteins were identified from both phases - Five proteins AHSG, APOL1, KNG1, VDBP and VN were differentially expressed - Further cross validation using iTRAQ and Western blotting showed AHSG and APOL1 could be potential growth hormone responsive markers in athletes	Tan <i>et al.</i> (2017)
Panizza E <i>et al.</i>	2017	Identification of low abundance phospho-proteins using HeLa cells	Phospho-peptide enriched samples labelled with TMT tags were subjected to high-resolution isoelectric focusing (HRIEF) and examined by LC-MS/MS analysis	- This is a novel workflow for identification of low abundance phospho-proteins - Identified a total of 22,712 phosphorylation sites 19,075 (14,965 Serine, 2916 threonine and 1203 tyrosine) phosphorylation sites were localized with high confidence 1264 Novel sites (previously unreported) were identified	Panizza <i>et al.</i> (2017)
Wang DL <i>et al.</i>	2017	Breast cancer	Serum samples enriched for low abundant proteins were subjected to 2D-DIGE ^a and the separated proteins were transferred to the protein elution plate (PEP) and hexokinase (HK) activity was measured. Followed by measurement of protease activity using FITC-labelled casein as the protease substrate	- Several potential functional protein biomarkers were identified from breast cancer patient sera - The workflow used showcases functional proteomics technology	Wang <i>et al.</i> (2017)
Sun Z <i>et al.</i>	2016	Lung cancer	2D-DIGE was employed following which the samples were transferred to the PEP and HK activity was measured. Fractions with high HK activity were analysed by LC-MS/MS	- Many time-dependent hexokinase activity fractions were detected from both the normal and lung cancer sera - Multiple fractions showed a 10-fold difference between normal serum and lung cancer sera - Hexokinase regulation can provide a potential panel of biomarkers for lung cancer	Sun <i>et al.</i> (2016)

(Continued)

Table 3 Continued

Author	Year	Disease/cancer type/ application	IPG-IEF utilisation	Key findings/notes	References
Liu S <i>et al.</i>	2016	Cervical cancer	iTRAQ-labelled peptides were fractionated by IPG-IEF followed by MS analysis	1. MS analysis identified 3300 proteins of which 137 and 193 were found to be up-regulated down-regulated respectively. 2. LYN was significantly overexpressed in higher in cervical cancer tissues 3. LYN knockdown and overexpression studies showed that it could inhibit or promote migration, invasion and cell proliferation in vitro and in vivo	Liu <i>et al.</i> (2016)
Hsu TY <i>et al.</i>	2016	Edwards Syndrome (Trisomy 18) Pregnancies	Samples labelled with Cy Dye were subjected to 2D-DIGE. Spots with a fold change of more than ± 1.5 were selected for MS/MS analysis by MALDI-TOF/TOF	1. 12 Spots were chosen for MS/MS analysis 2. 5 Spots were successfully identified, of which APOA1 was up-regulated and four proteins, IGFBP-1, VDBP, TTR, and A1AT were down-regulated 3. Further validation of these results is required using a larger sample size	Hsu <i>et al.</i> (2016)
Nakamura S <i>et al.</i>	2015	Tumour samples from gastric, pancreatic, colon, ovarian, renal, breast, lung, hepatocellular, oesophageal, prostate and thyroid cancers	Samples were subjected to 2D-DIGE, following which MS/MS analysis of selected spots was carried out by using MALDI-TOF/TOF Proteomic studies were performed using a FLAG-LIX1L-expressing HEK-293 (HEK-293FLG-LIX1L) cell line	1. Oncogenic activity of LIX1L and associated proteins was carried out using proteomic analysis 2. LIX1L was found to be associated with C-p89 and C-p80 kDa protein complexes when the cytoplasmic fraction was not treated with RNAase 3. Among the complexes, high immunoreactivity was observed for RIOK1, NCL and PABPC4 4. MS analysis of the nuclear fraction identified DHX9, NCL and HNRNPL to be differentially-expressed 5. Along with several other experiments LIX1L was suggested to be a putative RNA-binding proteins with implications in for therapeutic approaches for targeting LIX1L in LIX1L-expressing cancer cells	Nakamura <i>et al.</i> (2015)

Wu JY <i>et al.</i>	2014	Gastric cancer	Cy Dye labelled samples were subjected to 2D-DIGE followed by MALDI-TOF MS analysis	15 proteins spots were examined. 10 proteins were excluded under the suspicion of PTMs as they were found in different locations - Five proteins, GRP78, GSTP1, APOA1, A1AT and GKN1 were confirmed and further validated by Western blotting and IHC as putative markers of gastric cancer 1371 proteins were identified in the screened pleural effusions from patients with malignant mesothelioma ($n=6$), lung adenocarcinoma ($n=6$), or benign mesotheliosis ($n=7$) - Seven candidates from the proteomic data (AKR1B10, APOC1, LGALS1, MYO7B, SOD2, TNC, and THBS1) were validated by ELISA in a larger group of patients with mesothelioma ($n=37$) or metastatic carcinomas ($n=25$) - Galectin 1, aldo-keto reductase 1B10, and apolipoprotein C-I were all identified as potential prognostic biomarkers for malignant mesothelioma	Wu <i>et al.</i> (2014)
Mundt F <i>et al.</i>	2014	Malignant mesothelioma	iTRAQ-labelled samples were subjected to HIRIEF. 72 fractions were collected and subjected to LC-MS/MS analysis	1371 proteins were identified in the screened pleural effusions from patients with malignant mesothelioma ($n=6$), lung adenocarcinoma ($n=6$), or benign mesotheliosis ($n=7$) - Seven candidates from the proteomic data (AKR1B10, APOC1, LGALS1, MYO7B, SOD2, TNC, and THBS1) were validated by ELISA in a larger group of patients with mesothelioma ($n=37$) or metastatic carcinomas ($n=25$) - Galectin 1, aldo-keto reductase 1B10, and apolipoprotein C-I were all identified as potential prognostic biomarkers for malignant mesothelioma	Mundt <i>et al.</i> (2014)
Cantor D <i>et al.</i>	2013	Colorectal cancers	A membrane-enriched protein sample from SW480 cells overexpressing integrin $\beta 6$ was separated by IPG-IEF and the resulting fractions were examined by LC-MS/MS	708 proteins were found to have significant change in expression 54 proteins previously proposed as cancer biomarkers were identified $\beta 6$ expression enhanced cell invasion and proteins involved in cancer-related pathways such as ILK and RAN	Cantor <i>et al.</i> (2013)

^a2D-DIGE: First-dimension separation is done using isoelectric focussing (IEF) which is facilitated by immobilized pH gradient (IPG) strips. The second dimension separation performed using a gel.

Note: Observe the variety of applications and ability to be incorporated to different biological investigations, from identifying expression changes in various disease models to phospho-peptide enrichment and identification. Please note that Table 3 only identifies a brief selection of studies in order to demonstrate the utility of workflows incorporating IPG-IEF.

growth factor-I (IGF-I) and N-terminal pro-peptide of type III collagen (P-III-NP) (Tan *et al.*, 2017). However, these tests are insufficiently specific to indict or exonerate an athlete as having been administered GH as they do not ameliorate the variability imparted by factors such as age, gender, sport, ethnicity and dosage concentration. Furthermore, the GH isoform test remains unable to detect the administration of purified, pituitary-derived GH, which is commercially-available. As a result, there was an unmet need to accurately identify the exogenous administration of GH to athletes (Tan *et al.*, 2017). In their study, Tan *et al.* (2017) aimed to identify novel markers of GH administration in athlete plasma samples by an unbiased proteomic screening approach. This approach employed gel-based and gel-free proteomic methods which were undertaken in parallel. A simplified outline of this workflow is shown in Fig. 4.

Tan *et al.* employed a simple antibody-based sample enrichment step by utilising a MARS Human 7 (MARS-7) depletion column to remove seven high-abundance plasma proteins (albumin, IgG, IgA, transferrin, haptoglobin, antitrypsin, and fibrinogen) which respectively equated to approximately 40–50% of total plasma protein (by weight) (Tan *et al.*, 2017). Following the removal of these abundant constituents, the flowthrough from MARS-7 immunodepletion was then analysed in an unbiased fashion by employing a parallel analysis of each sample by 2D-DIGE and iTRAQ-based LC-MS analysis (Tan *et al.*, 2017).

In order to minimise technical variability between the experiments, Tan *et al.* carried out the study in two independent phases, wherein the 112 individual plasma samples were separated into two equal groups of 56 (Tan *et al.*, 2017). In an effort to further

Fig. 4 Schematic overview of the proteomic workflow employed by Tan *et al.* The plasma samples were immunodepleted using a MARS-7 column with the flowthrough analysed in parallel by 2D-DIGE and iTRAQ LC-MS/MS. This was followed by peptide and protein identification, with subsequent validation performed upon of selected proteins. Reproduced from Tan, S.H., Lee, A., Pascovici, D., *et al.*, 2017. Plasma biomarker proteins for detection of human growth hormone administration in athletes. *Sci Rep* 7 (1), 10039.

reduce variation, Tan *et al.* created a pooled reference sample which was then incorporated into each DIGE gel to facilitate gel alignment and matching. By adopting these two simple approaches, Tan *et al.* estimated the coefficient of variation (CV) between 28 gels in this first phase of the study to be only 8% (Tan *et al.*, 2017), which was considered acceptable given the extent of sample handling involved in performing a DIGE experiment.

Following image analysis of DIGE gels, 195 proteins were found to be differentially expressed. Stringent selection criteria (Tan *et al.*, 2017) were then imposed upon on the candidate spots, leading to the selection of 54 spots for further analysis. Of these, only 52 spots were excised for identification by MALDI-MS/MS analysis. It is important to note that the remaining two spots were not visible when the gels were re-stained, resulting in their omission from MALDI-MS/MS analysis. This highlights one of the disadvantages of employing a gel-based approach, as some proteins may not bind to the dye used to visualise and excise protein spots for MS analysis. Of the 52 spots analysed by MS, 39 differentially-expressed proteins were identified, of which 20 were differentially expressed from both Phases. Among the identified proteins, APOL1, AHSG, KGN1, VDBP, and VN were also shown to be differentially expressed in the recombinant GH (rGH)-treated group from both analysis Phases. Subsequent analysis later showed that KNG1 and VN exhibited variable expression patterns between Phases 1 and 2, resulting in their exclusion from further evaluation (Tan *et al.*, 2017). Tan *et al.* reported that these varying expression patterns for KNG1 and VN could be a result of individual variability.

In this study, Tan *et al.* employed 2D-DIGE, an IPG-IEF methodology, to investigate the effects of rGH administration to athletes. 2D-DIGE is a robust and fairly simplistic method to evaluate protein samples, providing an in-depth view of the proteome whilst identifying differentially-expressed proteins (Tiwari and Tiwari, 2014; Abdallah *et al.*, 2012). To negate the issue of dynamic range, Tan *et al.* performed 2D-DIGE on plasma samples whose complexity had been reduced by pre-treatment on a MARS-7 immunodepletion column (Tan *et al.*, 2017). However, while immunodepletion columns are excellent in reducing sample complexity, they possess significant disadvantages such as those outlined in Table 1, which must be carefully considered. Encouragingly, Tan *et al.* demonstrated excellent reproducibility from the immunodepletion process, estimating that ~40%–50% of the total plasma proteins (by weight) had been successfully removed with a coefficient of variation of 3.5% (Tan *et al.*, 2017). This low coefficient of variation supports the experimental system and that conditions were tightly controlled during preliminary depletion of the plasma samples.

In addition to immunodepletion, the application of 2D-DIGE in this study further reduced sample complexity by providing two additional layers of separation (i.e., pI and mass) prior to identification of selected gel spots by MALDI-MS/MS. These separations reduced sample complexity by multiple folds, however it did not negate the co-migration of multiple proteins in a single spot (Tiwari and Tiwari, 2014; Abdallah *et al.*, 2012) or the inherent weaknesses of 2D-DIGE that were observed in this study. For example, AHSG and KNG1 proteins were concurrently identified from spot 1921 (Phase 1), and AHSG and VN proteins were identified from spot 1021 (Phase 2). Despite this observation, the results from the DIGE study identified several differentially-expressed proteins which outweighed the observation of co-migration in few gel-spots (Tan *et al.*, 2017).

In addition to 2D DIGE, Tan *et al.* employed iTRAQ LC-MS/MS, an independent approach, using pooled samples. Unlike 2D-DIGE which considers proteoforms as independent gel spots, iTRAQ protein quantitation is inferred from the detected tryptic peptides (Tan *et al.*, 2017). Using this approach, Tan *et al.* identified 385 proteins (Tan *et al.*, 2017). Upon imposing filtering restrictions of $a \geq \pm 1.2$ fold change ($p \leq 0.05$), ≥ 2 peptides match and 95% confidence, 7 unique proteins were found to be differentially expressed between the rGH-treated and placebo-treated (Group A) samples, whilst 10 unique proteins were found to be differentially-expressed between within the rGH-treated baseline against other time-points (Group B). Six proteins (APOL1, IGFBP-ALS, AFM, IGFBP 3, LUM, and ECM1) were found to be consistently different between Group A and Group B. Surprisingly, only APOL1 was similarly observed in the results of the 2D-DIGE analysis.

These 6 proteins that were identified by iTRAQ and the 3 proteins (APOL1, AHSG and VDBP) that were identified by 2-D DIGE were then proposed as rGH-dependent biomarkers of GH administration. Further statistical analysis showed that two proteins, APOL1 and AHSG, were found to be consistently GH-responsive within the 2D-DIGE studies and that this trend was also observed for APOL1 from the iTRAQ study (Tan *et al.*, 2017). However, AHSG did not show significant difference between rGH-treated and placebo-treated samples in iTRAQ analysis (Tan *et al.*, 2017). To confirm these expression changes, APOL1 and AHSG were evaluated by Western blotting which supported the proteomic results observed (Tan *et al.*, 2017). Unfortunately, AFM, IGFBP3, IGFBP-ALS, LUM and ECM1 proteins, which showed significant differential expression, were not evaluated by Western blotting (Tan *et al.*, 2017). Validation of these observations would be of value for clinical practices and should be evaluated by independent studies.

In summary, Tan *et al.* employed an unbiased proteomic approach to identify eight rGH-dependent plasma proteins. Two of these differentially expressed proteins (APOL1 and AHSG) had not been previously demonstrated to be GH-responsive and indicated potential clinical utility. These putative biomarkers were then validated by Western blotting to confirm both their identities and their expression patterns in the rGH- and placebo-treated subject cohorts (Tan *et al.*, 2017). We believe that independent studies on the remaining putative GH-responsive biomarkers would be of great value for clinical practices by providing an alternate method for detecting the administration of GH to athletes as a performance-enhancing drug.

Case Study II

In the second Case Study, we wish to demonstrate how IPG-IEF can be utilised to profile the technically-challenging membrane fraction of whole cell lysate, enriching low-abundance hydrophobic proteins for detection by LC-MS/MS. In our previously

- Step 1

- Step 2

- Step 3

Fig. 5 Schematic overview of the proteomic workflow employed in the study (Cantor *et al.*, 2013). There are three main steps to the workflow presented. The first involved the culturing of at least 10^8 cells per cell line and strip range, followed by cell lysis, membrane protein enrichment, ultracentrifugation to precipitate the membrane-enriched fraction, sample reduction, alkylation and finally methanol-assisted tryptic digestion. The second step consisted of rehydrating the IPG-IEF strips with the peptide sample, followed by iso-electric focussing, before strip fractionation and elution. The third step of the workflow involved the elution of digested peptides out of the gel strip followed by sample clean-up, MS analysis, peptide identification and bioinformatics analysis.

published work, Cantor *et al.* (2013) generated a proteomic profile of CRC cell lines in order to determine the effect/s of induced expression of a suspected driver of CRC aggression (Cantor *et al.*, 2013). This was achieved by enriching CRC cell lysates for membrane-associated proteins by performing a 0.1 M sodium carbonate wash followed by ultracentrifugation, and has been displayed in a workflow schematic in Fig. 5 (Cantor *et al.*, 2013).

This simplified enrichment method was employed as integral- or peripheral membrane proteins are often under represented within proteomic studies due to a combination of low relative abundance and reduced aqueous solubility; yet it is the cell membrane which contains the greatest potential for drug targeting or biomarker identification as the plasma membrane contains the interface between the cell and the extracellular space (Yin and Flynn, 2016). Furthermore, integral membrane proteins have been suggested to constitute greater than 60% of current therapeutic targets (Yin and Flynn, 2016). Following reduction, alkylation and methanol-assisted tryptic digestion, the membrane-enriched lysate samples were focussed on linear IPG-IEF strips with pH ranges of 3–10 and 3.5–4.5, respectively, fractionated and desalted to remove MS-incompatible salts (Cantor *et al.*, 2013). Membrane-enriched peptides were then analysed by LC-MS/MS followed by the calculation of normalised spectral abundance factors (NSAF) to test for statistical significance.

Comparing the two cell lines found that 492 proteins were significantly up- or downregulated ($p < 0.05$) in the pH 3–10 dataset, whilst 263 proteins were significantly different in the pH 3.5–4.5 dataset (Cantor *et al.*, 2013). Interestingly, of these 263 additional proteins, 216 were unique to the pH3.5–4.5 strip range, illustrating that delving deeper into the acidic peptide population was able to bolster the number of proteins identified by 43%, identifying proteins that may have been masked in the broader pH3–10 range (Cantor *et al.*, 2013). In total, 708 proteins were significantly up- or downregulated between the two cell lines, potentially indicating a proteomic signature of inducing the expression of a key cancer-associated protein, the $\alpha v\beta 6$ integrin (Cantor *et al.*, 2013). Pairing sodium carbonate-based membrane protein enrichment with IPG-IEF resulted in the identification of 115 membrane proteins whose expression was significantly different in the pH3–10 dataset, potentially representing actionable biomarkers (Cantor *et al.*, 2013). Once again, the use of the narrower pH range of 3.5–4.5 afforded a deeper insight into the membrane proteome, identifying 186 membrane-associated proteins whose expression was significantly different between the two cell lines (Cantor *et al.*, 2013). This is likely due to fact that while membrane proteins are hydrophobic in nature, they invariably contain hydrophilic peptide sequences that interact with the aqueous environment.

IPG-IEF was a valuable component of this study, providing an inexpensive yet effective insight into the membrane proteome of CRC cell lines in order to identify significant shifts in protein expression that may promote CRC aggression and metastasis. Membrane proteomics has historically been regarded as being inherently difficult due to the nature of the highly hydrophobic sub-population and their relatively low abundance within the cell (Helbig *et al.*, 2010), however, IPG-IEF helped overcome some of these intrinsic challenges. Firstly, adopting IPG-IEF helped reduce sample complexity by providing an additional dimension of sample preparation by separating peptides based on pI prior to separation by reversed phase high performance liquid chromatography prior to in-line MS. By fractionating the sample into 24 pI-based fractions, each 70 min LC-MS/MS gradient was able to observe and fractionate a greater number of peptides than would have been possible for the unfractionated digest. Though this did not remove high-abundance proteins from the sample, low-abundance peptides from proteins of interest (i.e. the urokinase-type plasminogen activator receptor and the αv and $\beta 6$ subunits of the $\alpha v\beta 6$ integrin) were able to be identified by MS for the first time within our research group. Though protein depletion methods such as MARS-14 or immunoaffinity columns are also able to reduce sample complexity, there remains a risk of variable depletion efficiency between proteins (Tu *et al.*, 2010; Pernemalm *et al.*, 2008) and the concomitant loss of non-targeted proteins (Bellei *et al.*, 2011; Zolotarjova *et al.*, 2008). Both of these consequences must be tightly controlled in biomarker discovery studies and require the purchase of expensive consumables to be performed.

The workflow employed in this study was also able to overcome the challenges of membrane protein solubility without resorting to the use of detergents or other MS-incompatible solvents, which would require additional sample clean-up procedures. This in particular was a result of employing methanol-assisted tryptic digestion, wherein proteins were digested in a 60:40 mixture of LC-MS-grade methanol to reduced and alkylated protein preparation (Chick *et al.*, 2008). The use of methanol increases the mobility of integral membrane proteins, increasing tryptic access to cleavage sites that may be shielded by associated proteins or by their proximity to the plasma membrane itself. Methanol is easily removed during routine vacuum drying and provides an inexpensive alternative to detergents such as CHAPS or Triton X-114 which must be carefully removed prior to LC-MS/MS lest they damage the column prior to in-line MS and impede successful liquid chromatography. Though it can be performed without much technical difficulty, it must be mentioned that this label-free workflow was labour intensive, requiring a great deal of sample handling and the generation of considerable amounts of starting material (10–20 mg of lysate protein per cell line and strip range) in order to account for sample loss at each stage of the process. In summary, IPG-IEF proved to be a successful method from the extensive toolbox of proteomic methods and techniques, effectively delving into this particular niche of the CRC proteome.

Discussion

Identifying differentially-expressed proteins is a key requirement to elucidate the molecular processes of cells, tissues or organs, whether they are healthy, responding to hormone treatment or afflicted with diseases such as cancer. The importance of identifying differentially expressed proteins is that it can reveal the associated protein networks that are disturbed or significantly altered between biological conditions. This is particularly important when disturbances can be observed in protein networks responsible for cellular signalling activity or the governance of cellular behaviours such as growth, migration and death. Understanding these disturbed protein networks in cancer specimens can even yield clinically-relevant information such as the potential loss of avenues for therapeutic intervention.

For example, the expression or absence of the estrogen, progesterone and Her-2 receptors are used to classify breast cancers and guide treatment options. The absence of these three oncoproteins in a breast cancer specimen denotes a particularly heterogenous form of breast cancer ('triple-negative') that is characterised by poor clinical outcomes for patients and a lack of targeted treatment options for clinicians (Lawrence *et al.*, 2015). Therefore, there is little purpose in employing treatments that target the Her-2 receptor in order to antagonise triple-negative breast cancers which already lack the expression of the oncoprotein. However, proteomic analysis of the cancer tissue may reveal the molecular features of a tumour specimen and potentially indicate the presence of compensatory signalling pathway activity, such as that observed by Lawrence *et al.* in the Akt1/2 pathway, which may then serve as a personalised option for treatment (Lawrence *et al.*, 2015). Strategies such as those employed by Lawrence *et al.* (2015), have successfully sought to quantify signalling proteins, biological pathways and biomarkers by mass spectrometry. However, despite their extensive study, Lawrence *et al.* employed a very simple sample preparation workflow involving lysis, brief centrifugation, reduction and alkylation followed by digestion with Lys-C or trypsin, desalting and stepped high-pH RP-HPLC prior to LC-MS/MS. Though understandable to adopt a

simple shotgun proteomic workflow given the extensive amount of work performed in their study, Lawrence *et al.* were still only able to identify 12,775 distinct proteins encoded by 11,466 out of the estimated 20,537 genes (~56%) with a protein false discovery rate of <1%. Thus, despite significant advances from identifying ~3000 proteins per sample from our study in 2013 to ~9000 for each of the twenty samples in 2015 (Lawrence *et al.*, 2015), there remains a great need to increase proteomic coverage in order to identify the technically-challenging or low-abundance biomarkers that remain undetected.

Therefore, linking sequential protein separation methodologies such as IPG-IEF with RP-HPLC fractionation or Hi-Res IPG-IEF stands to greatly increase proteomic coverage (Griffel, 1970). However, this consequently increases sample processing time and may introduce additional layers of handling-based technical variation; both of which are not ideal for biomarker studies. In spite of this, there is no current workflow which can sufficiently overcome all the various challenges of the human proteome. Despite the need to manage the strengths and weaknesses of respective workflows, MS-based methods stand to become increasingly quantitative, meeting the sensitivity and speed to measure proteomes at depths that are comparable to gene expression studies (Lawrence *et al.*, 2015; Kim *et al.*, 2014; Wilhelm *et al.*, 2014). Paired with specific sample preparation and fractionation methods, MS-based investigations are providing an increasingly favoured platform for biomarker discovery compared to the more traditional antibody-based methods. One of the key strengths of MS-based studies is the specificity of the analyte being detected; whilst antibodies recognise a three dimensional epitope that is susceptible to denaturation or proteolysis, MS provides a much more robust *m/z* value, corresponding to the specific mass and charge state for each ionised peptide detected. Though a protein may be degraded by uncontrolled proteolysis, the *m/z* value of a digested peptide will remain unique to that amino acid sequence, whilst remaining unaffected by denaturation of the secondary/tertiary protein structure; a factor that could prevent the formation of the antibody/antigen complex. Though MS-based methods excel at identifying the amino acid sequence of a peptide, they are less capable of identifying the extensive array of post-translational modifications (PTMs) that can occur during protein maturation. These variable structures and less predictable fragmentation patterns are much more difficult to identify from spectra. On the other hand, antibodies can be raised against phosphorylated or glycosylated forms of proteins and detected much more easily and efficiently. MS-based methods are also highly dependent upon the properties of the instrumentation. For example, quadrupole mass spectrometers exhibit greater mass ranges and resolution than ion trap instruments. Time-of-flight-based instruments demonstrate greater mass ranges again and are much faster; however, this comes at the cost of lower resolution and difficulty in adapting to electrospray ionisation. As a result, MS platforms must be carefully chosen in order to ensure that they possess the required capabilities for analysis.

Future Directions

Antibody-based methods have been routinely used in the previous decades of biomolecular research as they offered the ability to be signal-amplifying, detecting small quantities amongst a complex and heterogeneous background which early MS-based approaches had difficulty penetrating. It has only been in recent years with the adoption of efficient sample fractionation methodologies and the continual development of increasingly sensitive and selective MS instruments that MS-based methods have begun to surpass those requiring the use of antibodies.

In this article, we have explored IPG-IEF and its related techniques as a means to identify differentially-expressed proteins that would enable researchers to peer deeper into the observable proteome, shedding further insight into the molecular biology of cells and tissues. Once a distinct set of proteins have been observed to consistently reflect a pathological condition such as disease or cancer, it then will become necessary to validate these potential biomarkers by highly-selective MS methods such as SRM, MRM or sequential window acquisition of all theoretical mass spectra (SWATH) to ensure that the relative shift in protein expression can reproducibly indicate the presence of disease. As data-independent acquisition (DIA) methods such as SWATH begin to supersede most traditional proteomic technologies in the study of whole proteomes, it is important to recognise that it is a costly exercise to generate spectral libraries in order to perform full DIA-based analysis on a patient by patient basis, both in terms of financial cost and the time required.

Despite their weaknesses, MS-based methods are becoming increasingly economical once the capital equipment (i.e., mass spectrometer) has been purchased, with day to day running costs being relatively inexpensive as opposed to the necessity to purchase antibodies and specialised reagents for methods such as ELISA. Furthermore the use of MS-based proteomic workflows counters a key weakness of antibody-based methods which depend upon the availability of specific antibodies (either as a single or pair) which possess sufficient specificity for the analyte. High specificity is a crucial requirement as poor specificity can result in reduced sensitivity, leading to false positive/negative results. This issue also extends to the fact that immunoassays are multi-staged processes that are susceptible to batch-to-batch variation of the antibody itself, with a greater potential for challenges to both intra- and inter-lab reproducibility compared to MS-based workflows. MS-based investigations also stand to facilitate the analysis of smaller sample volumes than methods such as ELISA, requiring smaller sample amounts whilst also enabling further characterisation of the antigen beyond mere abundance. This is afforded by providing sequence identification and potential analysis of protein isoforms and post-translational modifications, which cannot be supported by immunoassays. Whilst both platforms offer the opportunity to multiplex assays, immunoassays offer the simultaneous detection of 92 human proteins by utilising the Olink Proseek proximity extension assays whilst MS is capable of detecting 12,775 distinct protein species (Lawrence *et al.*, 2015; Mahboob *et al.*, 2015).

The continual development and refinement of tools and techniques are helping to reshape the field of proteomics from a role of investigative discovery in biomedical research to a first-response clinical tool (Cantor *et al.*, 2015). These developments support the use of MS as a primary technology in biomarker discovery as protein identifications must be robust, capable of identifying a specific peptide or single reaction monitoring (SRM) transition which may be inherently variable as a result of post-translational

modifications or glycosylation. MS stands as an effective method to identify differentially-expressed proteins in a manner that is reproducible between patients and institutions, in order to establish proteins of interest as clinically-relevant biomarkers.

Closing Remarks

All diseases involve proteins and networks of proteins, be it directly or indirectly. As a result, the relative flux of protein populations can be employed as biological insights into disease. However, the key challenge that faces biomedical researchers is the difficulty of finding that one protein of interest amongst the billions of somatic house-keeping proteins that constitute >99% of the cellular proteome. By continuing to drill deeper, it is hoped that the field of proteomics can generate more extensively characterised interpretations of what is occurring both within and between cells. It is the hope that these shifts in expression may ultimately be utilised as a clinical tool, either as a routine diagnostic or surveillance method, indicating the development of a disease before the onset of symptoms and thereby affording clinicians the best chance for a favourable patient outcome.

Acknowledgement

The authors would like to greatly thank Dr. Abidali Mohamedali (Macquarie University, Australia) for proof-reading the manuscript prior to submission. This manuscript has been prepared by the authors in their own time, with each contributing to the text. The authors declare that they received neither financial nor material assistance for the preparation of this work.

Appendix 1: List of gene abbreviations used in the article

<i>Abbreviation</i>	<i>Gene Name</i>	<i>Protein name</i>	<i>UniProtKB accession number</i>
AFM	AFM	Afamin	P43652
AHSG	AHSG	Alpha-2-HS-glycoprotein	P02765
AKR1B10	AKR1B10	Aldo-keto reductase family 1 member B10	O60218
APOA1	APOA1	Apolipoprotein A1	P02647
APOC1	APOC1	Apolipoprotein C-I	P02654
APOL1	APOL1	Apolipoprotein L1	O14791
N-p150	DHX9	ATP-dependent RNA helicase A	Q08211
ECM1	ECM1	Extracellular matrix protein 1	Q16610
VDBP	GC	Vitamin D-binding protein	P02774
GKN1	GKN1	Gastrophilin-1	Q9NS71
GSTP1	GSTP1	Glutathione S-transferase P	P09211
N-p68	HNRNPL	Heterogeneous nuclear ribonucleoprotein L	P14866
GRP78	HSPA5	78 kDa glucose-regulated protein	P11021
IGFBP-1	IGFBP1	Insulin-like growth factor-binding protein 1	P08833
IGFBP3	IGFBP3	Insulin-like growth factor-binding protein 3	P17936
IGFBP-ALS	IGFBPALS	Insulin-like growth factor-binding protein complex acid labile subunit	P35858
ILK	ILK	Integrin-linked protein kinase	Q13418
KGN1	KNG1	Kininogen-1	P01042
LGALS1	LGALS1	Galectin-1	P09382
LIX1L	LIX1L	LIX1-like protein	Q8IVB5
LUM	LUM	Lumican	P51884
LYN	LYN	Tyrosine-protein kinase Lyn	P07948
MYO7B	MYO7B	Myosin-VIIb	Q6PIF6
C-p90	NCL	Nucleolin	P19338
PABPC4	PABPC4	Polyadenylate-binding protein 4	Q13310
RAN	RAN	GTP-binding nuclear protein Ran	P62826
C-p89	RIOK1	Serine/threonine-protein kinase RIO1	Q9BRS2
A1AT	SERPINA1	Alpha-1-antitrypsin	P01009
SOD2	SOD2	Superoxide dismutase, mitochondrial	P04179
THBS1	THBS1	Thrombospondin-1	P07996
TNC	TNC	Tenascin-C	P24821
TTR	TTR	Transthyretin	P02766
VN	VTN	Vitronectin	P04004

Biographical Sketch

David Cantor is a Scientific Officer with extensive experience in proteomic research. After being awarded a Bachelor of Medical Science (Hons) from Macquarie University in 2011, he undertook a PhD in Biomedical Sciences, investigating the role of the $\alpha v \beta 6$ in integrin in colorectal cancer. During this project, he performed an array of proteomic and phenotypic studies in order to elucidate the molecular biology of this putative oncogene. After being awarded his PhD in 2017, he has been responsible for the preparation and analysis of various samples/specimens within the Australian Proteome Analysis Facility (APAF). He has trained multiple students in the performance of IPG-IEF and other proteomic workflows and has authored or co-authored several scientific publications in the field.

Harish Cheruku is a PhD graduate with extensive experience in proteomic research. After being awarded a Master of Biotechnology from Macquarie University in 2010, he worked as a Research Assistant and continued on to a PhD in Biomedical Sciences, investigating the biology of transforming growth factor-beta (TGF β) in colorectal cancer. He utilised an extensive set of proteomic tools to elucidate the effects TGF β in colorectal cancer during his PhD which was awarded in 2017. He has extensive experience in label-free and label-based proteomic workflows in addition to various cell and molecular biology techniques. He has authored or co-authored several scientific publications in the field.

Clinical Proteomics

Introduction

Clinical proteomics is the study of the entire protein content measured in patient's samples at a specific state or condition. Its primary goal is to analyze global protein profile of a biological system (cells, tissues, fluids) at a specific time point and state to confirm diagnosis, monitor treatment, screen for diseases, and take prognostic medical decisions (He and Chiu, 2003; Kulasingham and Diamandis, 2008a,b). The term "clinical" comes from the Greek word "klinike," which means "bedside," and the term "proteomics" is derived from both "proteome" and "omics" referring to the large-scale study of proteins including modified structures, variants, and mutations collectively called "proteoforms" (Schmit *et al.*, 2017; Toby *et al.*, 2016; Patrie, 2016; Wasinger *et al.*, 1995; Wilkins *et al.*, 1996a,b; Trenchevska *et al.*, 2016; Thygesen *et al.*, 2018). There is currently a tremendous amount of discoveries and information on proteins derived by mass spectrometry (MS) that can be applied in the clinic and can eventually revolutionize medical sciences and treatment. Although the amount of clinical proteomic profiles generated by MS measurements is remarkably increasing during the past two decades as indicated by the increase in rate of publications (Fig. 1), there is still a current gap between the patient's proteome profile and the real time conversion of these protein data into a more meaningful format that can reliably be applied in the clinics (Geyer *et al.*, 2017; Carvalho *et al.*, 2015; Lisitsa *et al.*, 2014; Kelleher *et al.*, 2014).

Multiparametric Panel of Proteome Profiles

Traditional clinical biochemistry relies on laboratory investigation results based on only a few single individual protein biomarkers, such as alanine aminotransferase (in liver function test), albumin, and creatinine (in kidney function test) among many others, to diagnose, treat, and monitor diseases while clinical proteomics considers profiling, which is the detection of panels of multiple biomarkers that provide more sensitivities and specificities (Penn *et al.*, 2018; Geyer *et al.*, 2017). In an era of information deluge with increasing data storage capacity and faster computational capability, the current challenge is how to increase further the technological advancement in proteomics instrumentation and data processing. The multiparametric and global nature of proteomic profiles derived from a patient's sample requires translation into a more useful form that is clinically relevant and more suitable in making diagnostic and prognostic decisions over the health status of patients (Matthiesen and Carvalho, 2013; Matthiesen, 2013a,b). This means increasing the sensitivity and robustness of MS-based instruments coupled with good experimental design standardized sampling techniques and more powerful bioinformatics analysis. This is necessary to generate accurate multiple biomarker profile panels that truly reflect the entire complement of proteins at a given particular state and condition (Matthiesen and Carvalho, 2013; Matthiesen and Bunkenborg, 2013; Penn *et al.*, 2018).

Fig. 1 Clinical proteomics and CRISPR/Cas9 literature review comparison. Total number of publications using MS-based clinical proteomics (blue) in comparison with the total number of publications in CRISPR/Cas9 (red), which is a technology that revolutionized genome editing recently and driving the medical field towards personalized treatments.

Fig. 2 Pathway from genome to proteome. Proteome is the entire complement of proteins including modifications produced by an organism or system. This set of proteins varies with time, physiological condition, and exposure to environment including stress that the cell or organism experience. Comparing between genome and proteome, genomics focuses on products of replicating the genetic code from DNA to another DNA mediated by DNA polymerase. Transcriptomics studies the products after transcribing DNA to RNA by the action of RNA polymerase. Proteomics, on the other hand, investigates the products of protein synthesis that uses the genetic code in RNA to produce proteins through ribosomal activity. The human genome is static over time with approximately 20,000 genes, which can be amplified by polymerase chain reaction (PCR), while the human proteome is dynamic that changes over time with more than 1,000,000 different proteins (according to the partial proteome map published in 2014) that determine functionalities of cells, tissues, and the human body.

Post-Translational Modifications in Proteoforms

Following the identification of about 20,500 genes after the completion of the human genome sequence in the year 2000, the “omics” era including genomics, transcriptomics, metabolomics, and proteomics began to receive a lot more attention (Van Karnebeek *et al.*, 2018; Piening *et al.*, 2018; Lacoste, 2018). The focus of scientific efforts has shifted from the human genome towards identifying the entire human proteome and measuring all the coded proteins and proteoforms (Fig. 2). Each gene gives rise to many proteins of various derivatives and alterations that cater to a particular specific functional role for homeostasis maintenance of the body’s biological processes. These functional alterations are achieved by differential RNA splicing and post-translational modifications (PTM), such as phosphorylation, glycosylation, acetylation, proteolytic processing, and numerous other types of PTMs that can diversify protein structure, conformation, and functionalities to produce over a million types of proteins comprising the entire human proteome (Nickchi *et al.*, 2015; Sergeant *et al.*, 2017). Simultaneously analyzing multiple changes in PTMs by quantitative PTMomics is useful for biomarker discovery and disease mechanisms elucidation using low amounts of tissue or body fluids (Thygesen *et al.*, 2018). Diseases occur with deviation from the normal homeostatic metabolic processes resulting in specific and detectable changes in protein profiles. Thus, direct measurements of the global protein changes can be performed by MS to determine both the diseased and normal states of the human body. The protein patterns in a patient sample correlate with disease characteristics that can predict clinical outcomes. However, the changes in protein levels are more complex and dynamic than that of genomics as they are easily influenced by several factors such as disease occurrence, environmental changes, diet or biological perturbations, and the combinatorial interactions among these factors. It is for this reason that to gain clinical acceptance, the use of protein profiles requires improvement in its disease-specificity and sensitivity by reducing non-disease-related variables. Under personalized medicine, each individual serves as their own control across various time points of protein measurements that look for any quantitative difference in abundance from the baseline or before and after clinically relevant perturbations (Keshishian *et al.*, 2015).

Single Reactor in Sample Preparation

The most desirable techniques that address the limited availability of clinical samples are those with high sensitivity to detect protein profiles using the smallest amount of sample. The desirability of microanalytical procedure with miniaturization is defined by sample volume reduction that saves precious reagents and limits clinical sampling resulting in faster analysis time, and increased high throughput potential with possible automation of single-use devices that suppress contamination (Lion *et al.*, 2004). The use of a single-reactor in a pipette tip that is fitted with a variety of filters for protein digestion, separation, and purification (Kulak *et al.*, 2014) is less invasive showing improvement in the efficiency of sample preparation with minimal sample loss (Hughes *et al.*, 2014). To avoid protein alteration or contamination and to optimize protein digestion, a known concentration of samples is separated from reaction salts that impede readout and is stored at a specified temperature. Samples are labeled with

Fig. 3 Mass spectrometry-based clinical proteomics workflow from clinical sample acquisition and introduction to mass and data analysis. All mass analyzers use electromagnetic fields to manipulate gas-phase ions. Results are plotted as *spectra*, with mass-over-charge (m/z) on the X-axis and ion intensity on the Y-axis. The latter can be *absolute* (counts) or *relative*. The *ionization source* ensures that (a part) of the *sample* molecules are ionized and brought into the gas phase. The *detector* is an electron multiplier responsible for recording the presence of ions as signals that represent the abundance of the analyte. *Digitizers* (analog to digital converters, ADC) transform the continuous analog detector signal into a digital, discretized spectrum by data processing. The two *ion sources* are: (1) *MALDI* (matrix assisted laser desorption and ionization), which relies on matrix molecules alpha-cyano-hydroxycinnamic acid (CHCA), sinapinic acid (SA), 2,5-dihydroxybenzoic acid (DHB), and a pulsed nitrogen UV laser ($\nu=337$ nm) and produce singly charged peptide ions; and (2) *ESI* (Electrospray ionization), which heats the needle to 40–100°C to facilitate nebulization and evaporation, and produces multiple charged peptide ions (2^+ , 3^+ , 4^+). Mass analyzers include: (a) Time-of-flight (TOF) relates m/z to the velocity of the ion, and the speed to the travel time the field-free tube length; (b) ion trap (IT) operates by effectively trapping the ions in an oscillating electrical field achieving mass separation by ejecting only ions of a specific mass; (c) quadrupole (Q) uses a combined RF AC and DC current creating a high-pass mass filter between the first two rods and a low-pass mass filter between the other two rods permitting only a specific m/z interval; (d) *orbitrap* consists of an outer and inner coaxial electrode generating an electrostatic field in which the ions form an orbitally harmonic oscillation along the axis of the field where the frequency of the oscillation is inversely proportional to the m/z , and can again be calculated by Fourier transform. *Tandem mass spectrometry* (*MS/MS*, *MS²*) is accomplished by using two mass analyzers in series (tandem). The first mass analyzer performs the function of ion selector, by selectively allowing only ions of a given m/z to pass through while the second mass analyzer is situated after triggering fragmentation and is used in its normal capacity as a mass analyzer for the fragments.

stable isotopes for mass identification and data quantification with reference to the protein sequence databases and the peptide quantitative information (Bantscheff and Kuster, 2012; Bantscheff et al., 2012). Various methods have emerged in handling different types of samples. The range of human protein abundance is from 0.01 to 10,000 ppm (Wang et al., 2012) with high abundance proteins such as extracellular matrix (ECM) in tissues masking the low abundance cellular proteins resulting in a narrow proteome coverage (Mann et al., 2013). For instance, differences of protein levels in normal and tumor tissues are measured and used to select against cancer cells that proliferate disproportionately and to identify drug targets or weak points in a cancer cell (Soldes et al., 1999a,b; Seow et al., 2001; Celis et al., 1999a,b,c, 2002; Celis and Gromov, 1999; Meehan et al., 2002; Franzen et al., 1997; Bini et al., 1997).

In sample handling (Fig. 3), storage conditions affect the serum peptidome MS profiles suggesting the importance of standardized blood sampling and storage for biobanks and interlaboratory multistudies using serum samples. Variations in proteome profiles can be avoided by standardizing sample collection considering the time between venipuncture and serum preparation that affects peptidome patterns (Tsuchida et al., 2018). Targeted in situ peptide fractionation in shotgun proteomics aims to reduce the complexity of peptide mixtures. This is achieved by selective enrichment of those digested peptides that possess specific features enabling them to bind into functionalized filter material in pipette tips. The nonbinding nontargeted peptides flow through as

unbound fraction after digestion. A good example for this is the CS-trap sample preparation method (Zougman and Banks, 2015), which uses the quartz depth filter surface functionalized with the pyridyl-dithiol group thereby allowing reversible in situ capture of the peptides with cysteines in the suspension trap-based digest (Zougman and Banks, 2015).

Human Tissue Samples

Protein analysis is carried out in two types of human tissue samples, frozen and formalin-fixed paraffin-embedded tissues (FFPE) (Wisniewski, 2013; Wisniewski *et al.*, 2013). Cancer diagnosis is generally dependent upon the FFPE with properly preserved tissue morphology and good staining. FFPE works with majority of the tissues for easy maintenance and long-term storage (Fox *et al.*, 1985). However protein profiles vary in samples that are processed differently at the preanalytical phase such as the time interval between tissue removal from the body and stabilization affecting data quality. Moreover, tissues collected from different patients exhibit variation in protein levels (Becker, 2015). Differences in protein profiles due to a disease and its progression are influenced by the procedural variables. Hence, the preanalytical phase involving sample collection, handling (transport, stabilization), storage, and analyte extraction need standardization to increase the sample quality and consistency (Fig. 3). Performing histological examination on samples prior to protein extraction to verify the cell structure and adopting an internationally standard step-by-step process of preanalytical assay are important for a systematized workflow (Becker, 2015) (Fig. 3).

Assessing tissues for cancer studies is challenging because they are comprised of cell populations that are a mixture of neoplastic and nonneoplastic cells. To overcome the difficulty of detecting indistinct signals due to the noise from surrounding cells, the laser capture tissue microdissection and cell sorting are now extensively used (Cecconi *et al.*, 2011a,b). Microanalysis handling of minute quantities of samples improves analytical performance with reduced sampling volume and faster time to obtain results (Lion *et al.*, 2004). In handling formalin-fixed paraffin-embedded (FFPE) tissues, the quality of protein profiles measured by label-free MS is less affected by the length of archival storage time for tissues, thus supporting their use in biomarker discovery and validation studies (Craven *et al.*, 2013). This will make the millions of FFPE tissues stored in biobanks a practical source of proteomic samples.

Enrichment of Low Abundance Proteins

Biological fluids contain a wide range of protein levels having the high-abundant proteins obscuring the detection of low-abundant proteins. The approach to mitigate this challenge is to remove the overabundant proteins thereby reducing the dynamic range of protein levels in the sample. Antibody-based affinity is used for selective removal of unwanted highly abundance specific proteins by binding the unwanted proteins to recover the flow-through consisting of low abundance proteins. Multiple affinity removal system is used in biological fluid proteomics to deplete abundant proteins by bundling to the carrier proteins thereby enriching detection of low abundance deep proteome (Krief *et al.*, 2012; Darde *et al.*, 2007). To address this, the affinity bound fraction is analyzed doubling the number of samples entering the downstream process (Giorgianni and Beranova-Giorgianni, 2016). Another method of reducing the level of high-abundant proteins is through the use of dynamic range compression that uses combinatorial ligand libraries in capturing and preferentially enriching low-abundant proteins (Righetti and Boschetti, 2008). This approach allows equalization of all proteins where high-abundant proteins are decreased and low-abundant proteins are boosted (Giorgianni and Beranova-Giorgianni, 2016). Another alternative technique is by using biochemical fractionation where peptides or proteins are divided into several fractions thereby reducing complexity in each fraction (Keshishian *et al.*, 2015). Sampling of body fluids for discovery and development of new biomarkers is in a form of serum/plasma, urine, cerebrospinal fluid, saliva, or bronchoalveolar lavage fluid. Prior to processing, the nonprotein elements are removed including the impurities such as cell debris, salts, lipids, and other minute molecular components. Fluids containing very low protein level undergo initial centrifugation to remove particles and contaminants followed by concentration of protein analytes and cleaning by either ultrafiltration with membrane filters or by protein precipitation with acetone or trichloroacetic acid.

Clinical Sample Processing: Electrospray Ionization and Matrix-Assisted Laser Desorption/Ionization

Proteomics by MS has two major approaches, comprehensive and targeted proteomics, which generally follow a workflow that includes sample preparation, protein extraction, protein digestion, peptide separation, mass analysis, and protein identification, validation, and biochemical characterization (Fig. 3). Comprehensive proteomics aims to identify all proteins in a sample using search algorithms like Mascot, Andromeda, SEQUEST, and so on (see Table 1). Targeted proteomics is used to program mass spectrometers into analyzing the preselected set of peptides produced by cleaving target proteins with Trypsin, LysC, or other proteases (Tsiatsiani and Heck, 2015).

Various samples, such as, cells, tissues, or body fluids, have been used in proteomics to characterize the entire protein content (Aebersold and Mann, 2016; Aebersold *et al.*, 2016). These samples are analyzed to diagnose particular diseases using an array of potential protein biomarkers measured that can indicate the incidence of outcome or disease (Ruhaak *et al.*, 2016). A promising biomarker molecule must exhibit precision, sensitivity, and reproducibility (Chahrour *et al.*, 2015) as accurately quantified by

Table 1 List of bioinformatics tools useful for clinical proteomics

Bioinformatics tools	Website/Source	Description
A-Score	https://www.ncbi.nlm.nih.gov/pubmed/16964243	A probability-based score that measures the probability of correct phosphorylation site localization based on the presence and intensity of site-determining ions in MS/MS spectra (Beausoleil <i>et al.</i> , 2006).
Andromeda	https://omictools.com/andromeda-tool	A peptide search engine based on probabilistic scoring with performance similar to Mascot that handles data with arbitrarily high fragment mass accuracy, assigns and scores complex patterns of PTM, and accommodates extremely large databases (Cox <i>et al.</i> , 2011).
APOSTL	https://github.com/bornea/APOSTL	Automated Processing of SAINT Templated Layouts (APOSTL) is a freely available Galaxy-integrated software suite and analysis pipeline for reproducible, interactive analysis of affinity proteomics (AP-MS) data using Galaxy workflows, which are intuitive for the user to move from raw data to publication-quality figures within a single interface.
Bio-TDS	http://biotds.org/	Bio-TDS (Bioscience Query Tool Discovery Systems) assists researchers in retrieving the most applicable analytic tools by allowing them to formulate their questions as free text using a flexible retrieval system that affords users from multiple bioscience domains (e.g., genomic, proteomic, bioimaging) the ability to query over 12,000 analytic tool descriptions integrated from well-established, community repositories.
CPAS	https://www.ncbi.nlm.nih.gov/pubmed/16396501	The open-source Computational Proteomics Analysis System contains an entire data analysis and management pipeline for liquid chromatography tandem mass spectrometry (LC-MS/MS) proteomics, including experiment annotation, protein database searching and sequence management, and mining LC-MS/MS peptide and protein identifications featuring general experiment annotation component, installation software, and data security management useful for collaborative projects across geographical locations and for proteomics laboratories without substantial computational support (Rauch <i>et al.</i> , 2006).
DBToolKit	http://genesis.Ugent.be/dbtoolkit/	DBToolKit allows the processing of protein sequence databases to peptide-centric sequence databases to enhance optimized search spaces for efficient identification of peptide fragmentation spectra obtained by mass spectrometry and for solving a range of other typical tasks in processing sequence databases (Martens <i>et al.</i> , 2005).
ExPASy	https://www.expasy.org/	SIB Bioinformatics Resource Portal that provides access to scientific databases and software tools in proteomics, genomics, phylogeny, systems biology, population genetics, transcriptomics (expasy.org).
gpmdb	http://gpmdb.thegpm.org	The Global Proteome Machine Database provides the information obtained by GPM servers to aid in validating peptide MS/MS spectra and protein coverage patterns, integrated into the GPM server pages allowing users to quickly compare their experimental results with the best results previously observed by other users of the machine (thegpm.org).
IDPicker	http://proteowizard.sourceforge.net/idpicker/	IDPicker views and filters peptide-spectrum-matches by reading and combining results from many different proteomic identification tools, including database search engines and spectral library matches.
InsPecT	https://bioinfo.ird.fr/index.php/resources/49-uncategorised/111-inspect	INSPECT (INtracellular ParasitE CounTer) is a free and open source software dedicated to automate quantification of <i>Leishmania</i> intracellular parasites based on fluorescent DNA images.
IntAct	https://www.ebi.ac.uk/intact/	IntAct provides a freely available, open source database system and analysis tools for molecular interaction data derived from literature curation or direct user submissions (ebi.ac.uk).
InterPro	https://www.ebi.ac.uk/interpro/	InterPro provides functional analysis of proteins by families, predicted domains and important sites with searchable resource for protein signatures from powerful integrated database and diagnostic tool (ebi.ac.uk).
itracker	https://www.ncbi.nlm.nih.gov/pmc/articles/PMC1276793/	i-Tracker software extracts reporter ion peak ratios from noncentroided tandem MS peak lists in a format easily linked to the results of protein identification tools such as Mascot and Sequest.
jPOSTTrepo	https://repository.jpostdb.org/	An international standard data repository for proteomes with a high-speed file uploading, flexible file management, and easy-to-use interfaces containing various proteomic datasets and is available for researchers worldwide.
MASCOT	http://www.matrixscience.com	A powerful search engine that integrates all of the proven methods of searching using the mass spectrometry data to identify proteins from primary sequence databases and serves as a benchmark for identification, characterization and quantitation of proteins. (matrixscience.com)
MaxQuant	http://www.biochem.mpg.de/5111795/maxquant	A quantitative proteomics software package that analyzes large-scale mass-spectrometric data sets using a set of algorithms that includes peak detection and scoring of peptides for mass calibration, database searching, protein identification, quantitation of identified proteins, and provision of summary statistics.
ModifiComb	https://www.ncbi.nlm.nih.gov/pubmed/16439352	Maps hundred types of PTM at a time including novel and unexpected PTMs.

(Continued)

Table 1 Continued

Bioinformatics tools	Website/Source	Description
MSAmanda	http://ms.imp.ac.at/?goto=msamanda	A scoring algorithm for high mass accuracy generally applicable to HCD, ETD, and CID fragmentation type data that provides free of charge both as stand alone version for integration into custom workflows and as a plugin for the Proteome Discoverer platform (Dorfer <i>et al.</i> , 2014).
msCompare	https://trac.nbic.nl/mscompare/ ,	A modular framework that allows the arbitrary combination of different feature detection/quantification and alignment/matching algorithms with a novel scoring method to evaluate their overall performance and to assess the performance of workflows built from modules of publicly available data processing packages such as SuperHirn, OpenMS, and MZmine.
mzIdentML	http://www.psdev.info/mzidentml .	Proteomics Standards Initiative mzIdentML open data standard captures the outputs of peptide and protein identification software supporting scores associated with localization of modifications on peptides, statistics performed at the level of peptides, identification of cross-linked peptides, and support for proteogenomics approaches.
neXtProt	https://www.nextprot.org)	The neXtProt human protein knowledgebase focuses on proteomics and genetic variation data for over 85% of the human proteins, as well as new tools tailored to the proteomics community including over 8000 phenotypic observations for over 4000 variations in a number of genes involved in hereditary cancers and channelopathies.
OMSSA	http://proteomicsresource.washington.edu/protocols06/omssa.php	A free search engine for analyzing and identifying peptides from tandem mass spectrometry (ms/ms) peptide spectra using the OMSSA algorithm that scores peptide hits using a probability-based method comparing experimental fragments with those calculated from libraries of known protein sequences (proteomicsresource.washington.edu).
Panther Classification System	http://pantherdb.org	The PANTHER (Protein ANALYSIS THrough Evolutionary Relationships) Classification System classifies proteins (and their genes) to facilitate high throughput analysis. The PANTHER Classifications are the result of human curation as well as sophisticated bioinformatics algorithms (pantherdb.org).
PaxDb	https://pax-db.org/about	A meta-resource of whole-organism and tissue-resolved data covering 85,000 proteins in 12 model organisms that integrates information on absolute protein abundance levels with emphasis on deep coverage, consistent postprocessing, and comparability across different organisms.
PDBe	http://www.ebi.ac.uk/pdbe/	(Protein Database Europe) European resource that provides the collection, organization and dissemination of data on macromolecular structures (ebi.ac.uk).
PEAKS	https://academic.oup.com/bioinformatics/article/23/2/243/204806	Analyzes any group of sequences that share a known reference element, such as the transcription start site, the initiation codon, a known TFBS or any other predefined site to detect any other motifs that show a significant clustering at a particular distance from the reference element, or sequence positions that show matches to motifs from a user-selected library.
PepNovo	http://proteomics.ucsd.edu/software-tools/531-2/	A high throughput de novo peptide sequencing analysis for tandem mass spectrometry (MS/MS) data that produces models of peptide fragmentation events by using a probabilistic network and a likelihood ratio hypothesis test to detect if peaks are produced under the fragmentation model or under a probabilistic model.
Peptide fragment fingerprinting	http://prowl.rockefeller.edu/prowl/pepfrag.html	PepFrag identifies proteins from a collection of sequences that matches a single tandem mass spectrum (expasy.org).
Peptide sequence database	http://pepbank.mgh.harvard.edu	Database of peptides based on sequence text mining and public peptide data sources that stores only peptides with 20 amino acids or shorter and with available sequences (pepbank.mgh.harvard.edu).
PeptideAtlas	http://www.peptideatlas.org	It is a multiorganism, publicly accessible compendium of peptides identified in a large set of tandem mass spectrometry experiments that provides output files collected from human, mouse, yeast, and several other organisms, searchable using the latest search engines and protein sequences containing the raw data, search results, and full builds (peptideatlas.org).
Peptidome (NCBI Peptide Data Resources)	http://www.ncbi.nlm.nih.gov/peptidome .	A public resource that archives and freely distributes tandem MS peptide and protein identification data generated by the scientific community, promotes sharing and dissemination of experimental data at a level of detail that is useful to both the specialized community and to the general biological community (ncbi.nlm.nih.gov).
Perseus	http://www.biochem.mpg.de/5111810/perseus	A software package for shotgun proteomics data analyses that extracts biologically meaningful information from processed raw files and performs bioinformatic analyses of the output of MaxQuant thereby completing the proteomics analysis pipeline (coxdocx.org).
Phenyx	http://www.ionsource.com/functional_reviews/Phenyx/phenyx-web.htm	Phenyx is a new sequence search engine based on the true probabilistic and flexible scoring system OLAV that uses mass spectrometry data to identify proteins and provide an automated second round search function.
PRIDE	https://www.ebi.ac.uk/pride/archive/	PRIDE database is a centralized, standards compliant, public data repository for proteomics data including protein and peptide identifications, PTM, supporting spectral evidence that provides a single point to submit MS-based proteomics data to public domain repositories (ebi.ac.uk).

Table 1 Continued

<i>Bioinformatics tools</i>	<i>Website/Source</i>	<i>Description</i>
ProDom	http://prodom.prabi.fr/prodom/current/html/home.php	ProDom is a comprehensive set of protein domain families automatically generated from the UniProt Knowledge Databases, constructed automatically by clustering homologous segments consisting of domain family entries that provides a multiple sequence alignment of homologous domains and a family consensus sequence (prodom.prabi.fr).
ProSite	https://prosite.expasy.org	Provides documentation entries describing protein domains, families and functional sites as well as associated patterns and profiles to identify them (prosite.expasy.org).
ProteinProphet	http://proteinprophet.sourceforge.net	ProteinProphet™ automatically validates protein identification made on the basis of peptides assigned to MS/MS spectra by database search programs such as SEQUEST.
ProteomicsDB	https://www.ProteomicsDB.org	A protein-centric in-memory database for the exploration of large collections of quantitative mass spectrometry-based proteomics data to enable the interactive exploration of the first draft of the human proteome.
Proteowizard	http://proteowizard.sourceforge.net	The ProteoWizard Library and Tools are a set of modular and extensible open source, cross-platform tools and software libraries that facilitate proteomics data analysis and enable rapid tool creation by providing a robust, pluggable development framework, which simplifies and unifies data file access, and performs standard chemistry and LCMS dataset computations.
PTM Score	http://www.bioinform.com/peaks-ptm/	Identifies and characterizes PTMs of proteins such as phosphorylation, ubiquitination, acetylation, and methylation that play critical roles in diverse biological processes such as signaling and regulatory processes, protein activity and degradation, regulation of gene expression essential for a comprehensive understanding of cellular biology and human diseases with a wide range of applications.
R	https://www.r-project.org	R is a free, software environment for statistical analysis, with many useful features that promote and facilitate reproducible research (r-project.org).
ROTS	https://www.bioconductor.org/packages/ROTS	The reproducibility-optimized test statistic adjusts a modified t-statistic according to the inherent properties of the data and provides a ranking of the features based on their statistical evidence for differential expression between two groups applicable in transcriptomics and proteomics.
SEQUEST	https://omictools.com/sequest-tool	SEQUEST provides fragmentation patterns in tandem mass spectra to detect AAS from protein and nucleotide database, correlates the spectrum and allows searches with the experimental data via the prediction of fragment ions of an AAS and offers to users the ability to correlate exactly uninterpreted tandem mass spectra to sequences in the database (omictools.com).
Skyline	http://proteome.gs.washington.edu/software/skyline	An open source and freely available windows client application for targeted proteomics method creation and quantitative data analysis that simplifies the development of mass spectrometer methods and the analysis of data from targeted proteomics experiments performed using SRM.
SMART	http://smart.embl-heidelberg.de	SMART (Simple Modular Architecture Research Tool) allows the identification and annotation of genetically mobile domains and the analysis of domain architectures (embl-heidelberg.de).
Spectrum Mill	https://www.agilent.com/en/products/software-informatics/masshunter-suite/masshunter-for-life-science-research/spectrum-mill	Spectrum Mill for MassHunter Workstation quickly identifies proteins and peptides through fast database searches with automatic or manual match validation and unique algorithms that minimize false positives, offers de novo spectral interpretation for proteins not found in databases, identifies relative abundance differences of two-fold or greater without complicated isotope labeling, and summarizes results in formats that provide maximum insight and convenience.
SWISS-PROT	https://web.expasy.org/docs/swiss-prot_guideline.html	Curated protein sequence database that provides a high level of annotation, minimal level of redundancy and high level of integration with other databases (Bairoch <i>et al.</i> , 2004).
TOPP	http://ftp.mi.fu-berlin.de/pub/OpenMS/release-documentation/html/index.html	TOPP (The OpenMS Proteomics Pipeline) provides a set of computational tools combined into easy analysis pipelines for nonexperts of proteomics workflows with useful utilities file format conversion, peak picking, and supports known applications (e.g., Mascot) to generate new algorithmic techniques for data reduction and data analysis.
TPP	http://tools.proteomecenter.org/wiki/index.php?title=Software:TPP	The Trans-Proteomic Pipeline is a collection of integrated tools for MS/MS proteomics developed at the SPC.
UniProt (universal Protein Resource)	http://www.uniprot.org	A comprehensive resource for protein sequence and annotation data that provides the scientific community with a comprehensive, high quality and freely accessible resource of protein sequence and functional information (Bairoch <i>et al.</i> , 2005) (uniprot.org).
X!Tandem	http://www.thegpm.org/TANDEM	X! Tandem open source is software that can match tandem mass spectra with peptide sequences in protein identification.
ZBIT Bioinformatics Toolbox	https://webservices.cs.uni-tuebingen.de/	The Center for Bioinformatics Tuebingen (ZBIT) Bioinformatics Toolbox provides web-based access to a collection of bioinformatics tools developed for systems biology, protein sequence annotation, and expression data analysis (Romer <i>et al.</i> , 2016).

proteomic technologies. Electrospray ionization (ESI) and matrix-assisted laser desorption/ionization (MALDI) are the two main technologies for sample processing in MS that focus on quantitative proteomics analysis. ESI processes neutral compounds to generate ions that are detected as mass/charge (m/z) ratio of each peptide, which is recorded by a computer and shown as a mass spectrum (Ho *et al.*, 2003). MALDI on the other hand uses a laser beam to light up a solid sample into an ionized form that travels through the mass spectrometer, detected and translated into the mass/charge (m/z) measurements (Andersson *et al.*, 2010; Duncan *et al.*, 2016). Variability of outcome in protein measurements depends on sample handling whereby protein denaturation, incomplete digestions, desalting, and depletion failures, which cause loss of pertinent data, need to be avoided (Buchler *et al.*, 2016). Both the molecular labeling method used to tag samples for quantification and the resolution capacity of MS also influence results, and thus need consideration early on in the experimental design prior to measurements (Tsuchida *et al.*, 2018). Quantification of targeted proteomics depends on selected or multiple reaction monitoring, which requires complex statistical analysis, and validation of the result is laborious. Several groups endeavor to improve the validation by developing the Sequential Windowed Acquisition of All Theoretical Fragment Ion Mass Spectra in combination with a nontargeted acquisition or combining different ion sources without any interference in a single mass spectrometer (Kostyukevich and Nikolaev, 2018).

Bottom-Up and Top-Down Proteomics

Proteomics is divided into two types of analysis based on whether the measurements are made on broken-to-pieces proteins (bottom-up proteomics) and intact proteins (top-down proteomics). Although top-down proteomics is advantageous for examining protein modifications, it is not as well-established as the bottom-up approach, facing more technical challenges as intact proteins are more complicated to handle with their poor solubility than peptides. Bottom-up or shotgun proteomics is easier to fractionate in liquid chromatography and easier to analyze in tandem mass spectrometer (LC-MS/MS) due to their smaller size and easier transfer to MS through ESI. Using proteases, proteins are first converted to small pieces of peptides, into which measurements are performed. Proteins are digested with trypsin that cleaves after every lysine and arginine residues resulting in truncated peptides of around 6–25 amino acids, although other proteases are also used. MS is then applied to measure the mass-to-charge ratio of each peptide in mixtures of thousands of peptides to determine the amino acid sequence. There are four stages of the process, consisting of sample preparation, separation of peptides, MS, and bioinformatics analysis of the data (Fig. 3). The critical factor in this approach is the sample preparation that requires protein fractionation or depletion methodologies to isolate low-abundant proteins. Peptide matches also need examination and manual validation for a series of consecutive sequence-specific b-type and y-type ions. Moreover, the correct peptide sequence and accurate quantification of proteins are achieved by using a newer generation of mass spectrometers with higher resolution. In targeted LC-MS/MS, a set of phenotypic/signature peptides containing the target protein sequences are selected using bioinformatics tools such as UniProt Database, ExPASy, PeptideAtlas, and so on (Table 1). The selected peptides are then synthesized as labeled internal standards (absolute quantification AQUA (Gerber *et al.*, 2007, 2003), QconCAT (Beynon *et al.*, 2014), PSAQ (Dupuis *et al.*, 2008)), chromatographed, eluted by ESI to MS, detected, and measured in available platform of LC-MS/MS (Fig. 3). Targeted MS/MS instruments include quadrupole-Orbitraps and quadrupole time-of-flight with high resolution of 140–240,000 and 100,000, and with mass accuracy of 2 ppm and 2–5 ppm, respectively.

Top-down proteomics identifies intact proteins containing PTMs including the truncated proteoforms translated from reference ORFs or alternative open reading frames (altORFs) increasing the size of the actual proteome. Top-down proteomics can provide the whole sequence information of the proteoforms useful in analyzing various structural modifications due to variations in genes, RNA, and proteins (Fig. 2). Top-down mass spectral database searches that align millions of spectra against thousands of protein sequences in high throughput proteome level analyses have been made available recently (Leduc *et al.*, 2018; Kou *et al.*, 2018). In MALDI-imaging or MALDI-IMS, proteins including their molecular arrangement in samples are analyzed. It can scan a broad range of protein from a tissue section at defined geometrical coordinates producing an ion-density map. A fresh-frozen tissue section is used resembling the real tissue where the relative abundance of the selected ion is displayed on a color-intensity scale at each coordinate location (pixel) (Seeley *et al.*, 2008). MALDI-IMS has limited mass range that detects only small proteins thus needing further enhancement. MALDI-TOF-MS provides a rapid technique to identify microorganisms useful in pathogenic bacteria taxonomy, clinical microbiology, and food safety (Fagerquist, 2017).

An important step in proteomics is validation that is needed in translating research into the clinic. Confirmation by Western blotting excludes false-positive results. The functional significance of the molecules involved is verified by *in vitro* or *in vivo* assays, which demonstrate inhibition or activation of the pathway followed by analysis of its biological effects. *In situ* validation uses antibodies to detect isoforms such as phosphorylated proteins at specific locations. Several antibodies are used to validate the various components of a pathway (Cecconi *et al.*, 2011b).

Personalized Proteomics and Precision Medicine

Currently drug prescription for patients is based on general information about what generally works. If the medication is not working then the patient is switched to another medicine based on trial and error, which sometimes results in adverse drug responses making patients suffer from side effects of unnecessary or inappropriate use of medications. This approach to treatment

is now changing with the progress made in personalized medicine. P4 medicine (preventive, predictive, personalized, and participatory) tailors medical treatment to the individual characteristics, needs, and preferences of a patient during all stages of care, including prevention, diagnosis, treatment, and follow-up (Tian *et al.*, 2012; Van Karnebeek *et al.*, 2018). The patient's treatment is catered upon their individual genetic makeup, entire genetic profile, and personalized proteomics data (Duarte and Spencer, 2016). Proteomics studies open the door for the clinicians to understand diseases at protein levels. A collection of protein data in combination with the DNA information provides insights into the development of therapies. Proteomics connects the gap between diagnostics and therapeutics by facilitating detection of protein biomarkers (Jain, 2016). Pharmaceutical industries use clinical proteomics to determine relevant drug targets, which are typically proteins that play many important roles in the metabolic pathways (Snyder *et al.*, 2014). The FDA and other agencies also request protein profiles in new drug development, attracting high interest for both for the healthcare sector, as well as the pharmaceutical and biotech industry (Szasz *et al.*, 2017; Marko-Varga and Labaer, 2017).

To illustrate the potential of proteomic analysis, a study was conducted in bladder cancer using different proteomic platforms. In bladder cancer cases, the degree of tumor spread into the bladder wall is classified into three different categories, namely non-muscle invasive, muscle invasive, and metastatic disease (Babjuk *et al.*, 2017). The monitoring device is invasive cystoscopy, which uses a thin camera to look inside the bladder of patients. However, having proteomics profiling of urine and tissues decreases the dependency on invasive cystoscopy improving bladder cancer patient management. In this example, the negative result avoids the unnecessary cystoscopy invasion while the positive result points to a more thorough examination. Tissue molecular profiling further revealed that bladder cancer is a highly heterogeneous disease with genetic alterations found in the adjoining tissues in bladder cancer patients (Thomsen *et al.*, 2017). Detailed assessment of molecular alterations indicates the direct site of disease initiation and progression thus is beneficial in identifying potential therapeutic targets and prediction of treatment response. Urine proteome profiling enables diagnosis, monitoring, and stratification by looking at the gradual change of the amount of urinary peptides as the cancer advances (Latosinska *et al.*, 2017a,b).

Several studies have utilized proteomics to identify biomarkers. For example, endogenous peptide of pleiotrophin was identified as a new biomarker of Alzheimer's disease (Blennow and Zetterberg, 2015). A group of Japanese researchers have also identified leucine-rich alpha-2 glycoprotein as a potential biomarker to diagnose Kawasaki disease based on proteomics analysis (Kimura *et al.*, 2017). High throughput verification of hundreds of biomarker candidate proteins to detect early stage colorectal cancer was done using targeted proteomics resulting in identification of the annexin family of proteins as promising colorectal cancer biomarker candidates (Shiromizu *et al.*, 2017). With the improvement and enhancements made in the proteomic technologies, workflows, computational tools, instruments, and availability of data obtained from other "omics" analysis, personalized medicine is now becoming possible although there are still limitations that need to be mitigated. Proteomics data are useful in designing a treatment plan distinct to the condition the individual experiences.

Proteform Bioinformatics

The Human Proteome Project (HPP) (see "Relevant Websites section") was created through the coordinated efforts of many research laboratories around the world with the goal of mapping the entire human proteome (Omenn *et al.*, 2017). It has two main goals: The comprehensive and systematic analysis of the human proteome map and the creation of analytical tools to measure proteins relevant in health and disease (Segura *et al.*, 2017). In 2014, two independent groups published the first draft of human proteome using many different tissues by MS, thereby, putting proteomics into the spotlight and laying a foundation for development of diagnostic, prognostic, therapeutic, and preventive medical applications. The advances in biology using technologies that produce high throughput data have fueled the development of systems biology. ProteomicsDB (see "Relevant Websites section") enables interactive use of the human proteome and its large quantitative MS database (Schmidt *et al.*, 2018). Powerful bioinformatics tools are much needed to enable new applications of proteomics data in precision medicine and in the clinics. JS-MS is a stand-alone cross-platform that enables 3-D visualization for MS data processing and evaluation (Rosen *et al.*, 2017).

The SWISS-PROT is an annotated protein sequence database created by A. Bairoch on 21 July 1986 that integrates with other databases at that time including EMBL Nucleotide Sequence Database, PDB (Protein Data Bank), PIR (Protein Identification Resource), HIV (the human retroviruses and AIDS Database), OMIM (the online version of the book *Mendelian Inheritance in Man*), PROSITE (the Dictionary of Protein Sites and Patterns), and REBASE (the database of type 2 restriction enzymes) (Bairoch and Boeckmann, 1991). The first software developed for 2DE image analysis in 1979 was ELSIE, which was followed by a vast array of current proteomics tools such as ExPASy, IntAct, InterPro, Matrix Science, OMSSA, Panther Classification System, PDBe (Protein Database Europe), PeptideAtlas, Peptidome (NCBI Peptide Data Resources), PRIDE, ProDom, ProSite, thegpmdb, SEQUEST, UniProt (universal Protein Resource), R, and SMART among many others (see Table 1). The neXtProt is a protein knowledgebase (see "Relevant Websites section") that focuses on proteomics and genetic variation data for over 85% of the human proteins, includes new proteomics tools and over 8000 phenotypic observations for over 4000 variations in genes involved in hereditary cancers and channelopathies, and provides an API access and a SPARQL endpoint for technical applications (Gaudet *et al.*, 2017).

Clinical proteomics involves a complex process that starts with sample extraction and processing, followed by protein and peptide fractionation, MS measurement, and finally protein identification and quantification (Fig. 3) (Mallick and Kuster, 2010).

The synergy of the high throughput MS-based proteomics data along with the network-based computational analysis has facilitated the investigation of the cellular networks associated with certain disease important to basic and clinical research (Schmidt *et al.*, 2014). Bioinformatics has provided the tools and methods necessary for processing genetic information from patients integrating the clinical, environmental and genetic data. It has played a vital role in generating, storing, and curating protein sequence databases, developing relevant software for the proteomics data analysis, integrating protein interaction networks, and consolidating data from other “omics” to produce a meaningful biological information (Felgueiras *et al.*, 2018; Uppal *et al.*, 2018).

Several steps are involved in bioinformatics, namely: (1) Collecting statistics from biological data, (2) building a computational model, (3) solving a computational modeling problem, and (4) testing and evaluating computational algorithm (Can, 2014). A successful analysis outcome is obtained by integrating proteomics data with other “omics” data using data-driven integration and network analysis tool such as xMWAS, for example (Uppal *et al.*, 2018). Various repositories have also been created such as PeptideAtlas (Desiere *et al.*, 2006; Deutsch *et al.*, 2005; Schwenk *et al.*, 2017), GPMDB (Craig *et al.*, 2006), PRoteomics IDentifications (PRIDE) (see “Relevant Websites section”) (Martens *et al.*, 2005; Vizcaino *et al.*, 2016a,b), UniProt (The Uniprot Consortium, 2018), and neXtProt (Gaudet *et al.*, 2017) among many others that store proteomics experimental information. These repositories were designed to be made publicly available and can be directly used or reused in producing novel findings, which would generate new knowledge (Jarnuczak and Vizcaino, 2017; Vizcaino *et al.*, 2017; Okuda *et al.*, 2017; Chen *et al.*, 2017; Keerthikumar and Mathivanan, 2017). These data can be used for investigation and mining to extract relevant, usable, and quality information for clinical application (Islam *et al.*, 2017). To assess the key steps of MS data analysis process, database search engines, and methods in quality control (QC), protein assembly and data integration, the entrapment sequence method has been used as the standard (Feng *et al.*, 2017).

The HPP provides MS and antibody-based data on all human proteins from various physiological and pathological conditions (Omenn *et al.*, 2017). For 15 years, the Proteomics Standards Initiative of the Human Proteome Organization (HUPO) has provided guidelines for sharing data sets to the public establishing open community standards and software tools for proteomics such as PSI-MI, XML, MITAB, mzML, mzIdentML, mzQuantML, mzTab, and the MIAPE (Minimum Information About a Proteomics Experiment) (Deutsch *et al.*, 2017). One of its key aspects is the use of standardized and well-defined terminology to complete the values in the data files (Mayer *et al.*, 2014). Moreover, two novel standard data formats (proBed and proBAM) for proteogenomics were recently developed with functionalities in file generation, file conversion, and data analysis (Menschaert *et al.*, 2018) improving the integration of genomics and proteomics information and the evaluation of peptide spectrum matches (PSM). An easy-to-use tool proBAMconvert (see “Relevant Websites section”) allows conversion of mzIdentML, mzTab, and pepXML file formats to proBAM/probed or output at PSM and peptide levels using a command line and graphical user interface (Olexiouk and Menschaert, 2017). Furthermore, several ongoing analytical designs are nearly completed including formats for a spectral library standard, a universal spectrum identifier, the qcML quality control, and the Protein Expression Interface web services Application Programming Interface in synergy with ProteomeXchange Consortium, HPP, and other “omics” community (Deutsch *et al.*, 2017). Additional initiatives such as multiorganism proteome (iMOP) (Tholey *et al.*, 2017), the Human Cancer Proteome Project (Cancer-HPP) (Jimenez *et al.*, 2018), the Human Eye Proteome Project (EyeOme) (Ahmad *et al.*, 2018), Chromosome-Centric Human Proteome Project (C-HPP) (Meyfour *et al.*, 2018), Human Immuno-Peptidome Project (Caron *et al.*, 2017), fecal proteome (Jin *et al.*, 2017) among many others are examples that support HPP in proteome research aimed at improving the human health using multiparameter diagnostics applicable for personalized medicine.

The Human Protein Atlas provides protein localization and expression data in human tissues and cells (Thul and Lindskog, 2018). It has a collection of antibodies to map the entire human proteome by immunohistochemistry and immunocytochemistry generating more than 10 million images of protein expression patterns at a single-cell level (see “Relevant Websites section”) (Thul and Lindskog, 2018). These resources can be freely accessed allowing scientists and clinicians to explore the human proteome. Public data sharing used to be problematic but is now becoming feasible encouraged by the scientific journals and funding agencies as part of good scientific practice (Spidlen and Brinkman, 2018) and enhanced by the availability of user-friendly online resources and tools (Perez-Riverol *et al.*, 2016a,b). To bypass difficulty of data sharing due to variable types of data formats, the PSI of the HUPO has lead the development of standard file formats and controlled vocabularies (Vizcaino *et al.*, 2017; Bittremieux *et al.*, 2017). A popular format is mzML, which stores raw MS data and processed peak list spectra (Martens *et al.*, 2011). The freely available pymzML (see “Relevant Websites section”) has optimized source code and data retrieval algorithms, provided faster random access to compressed files and quicker numerical calculations, suitable for large file sizes having a versatile scripting language (Kosters *et al.*, 2018). Another format is mzIdentML for peptide and protein identifications obtained from MS data that allows various software tools to communicate with each other (Vizcaino *et al.*, 2017). Moreover, the mzQuantML data standard format records detailed quantitative information (Walzer *et al.*, 2013) from a variety of popular discovery based workflows such as SILAC or dimethyl or MS2 tag based TMT or iTRAQ. This format is now able to store results from targeted techniques such as selected/parallel reaction monitoring (SRM). The ProteoWizard’s msConvert and msConvertGUI softwares are useful in converting data from vendor-specific propriety binary files generated by diverse mass spectrometers to open-format files (Adusumilli and Mallick, 2017). Recently a simpler text-based format called msTab was produced that stores both identification and quantification information (Griss *et al.*, 2014). It follows a tabular design making it simpler to load into a spreadsheet. MzTab is now supported as part of popular analysis tools such as PRIDE, MassIVE, and jPOST. The PRIDE Inspector Toolsuite is a freely available modular set of open-source cross-platform libraries for handling and visualizing different experimental output files including spectra (mzML, mzXML), peptide and protein identification data (mzIdentML, PRIDE XML, mzTab), and quantification data (mzTab, PRIDE XML) (see “Relevant Websites section”) (Perez-Riverol *et al.*, 2016b).

With open-access data, QC of proteomics has been given more importance and attention recently. Relevant software tools for performing QC are now available, which assess the consistency of the data submission in a form of correspondence between the mass spectra and identification results, detecting clear annotation errors, ensuring acceptable level of technical and biological metadata. Users of Pride Inspector, a freely available tool to browse MS proteomic data are also encouraged to flag any potential errors detected.

Bioinformatics plays a key role in various aspects of proteomics analysis including peptide-spectra matching (PSM) based on the new data-independent acquisition paradigm, resolving missing proteins, dealing with biological and technical heterogeneity in data and statistical feature selection. Further work is still required to enhance the proteomic analysis, performance, and reproducibility so that it can be applied in clinical medicine. More powerful bioinformatics tools with greater accuracy and resolution, faster protein identification algorithms, reduced false positives, and automated data validation capabilities that allow the consolidation of results from multiple studies will enable deeper understanding of the full proteome map of tissues or cells. Linking various omics is important to achieve proper interpretation of complex biological systems.

Conclusion

Examining the proteome is likened to getting a “snapshot” of the total protein environment at any given time point to have various insight into what is happening in the cell and how the cells are working. Interaction among proteins is a dynamic process that changes quickly over time but can be captured in proteome analysis to predict the underlying causes of diseases. The capability of time course proteomics data as a monitoring process is confirmed in several experiments such as the analysis of dynamic responses to ER stress in HeLa cell proteome (Cheng *et al.*, 2016), the discovery of different features of human metabolism in long-term space travel simulation experiments (Binder *et al.*, 2014), and the measurements of proteome dynamics in pathological cardiac hypertrophy model (Lau *et al.*, 2018) among many others. The proteome map illustrates beneficial information about the patients’ well being and the effectiveness of any drug administration for treatment. Through proteomics, molecules that affect drug target identification such as proteoforms and all modified proteins are characterized to develop more effective novel drugs with fewer side effects (Kuhlmann *et al.*, 2018; Daher and De Groot, 2018). Quantitative analysis of these proteoforms has been anticipated to deliver the next generation of multiparametric biomarkers applicable in personalized medicine (Mueller *et al.*, 2018). But approval of these biomarkers in the clinic requires a tremendous amount of work involving standardized collection of samples from patients towards simplifying the grand scale of the collected protein information into something that can easily be interpreted as useful by health care professionals (Schmit *et al.*, 2017; Nedelkov, 2017). Although faced with a lot of challenges, it is just a matter of time before the application of proteomics in personalized medicine by proteome profiling of an individual’s condition is achieved in a clinical setting. The use of bioinformatics in clinical proteomic research has not been exploited extensively as most have favored the wet lab based activities (Akhter and Shehu, 2018). However, big proteomics data generated would certainly bring benefits to the clinical environment particularly in the understanding of the molecular origins of pathologies and drug mechanisms (Trindade *et al.*, 2018).

Molecular Mechanisms Responsible for Drug Resistance

Mun Fai Loke and Aimi Hanafi, University of Malaya, Kuala Lumpur, Malaysia

© 2019 Elsevier Inc. All rights reserved.

Introduction

In general, drug resistance is the reduction in effectiveness of a medication or drug to cure a disease or condition. More commonly, antimicrobial resistance (also known as drug resistance) is the ability of microbes, such as bacteria, viruses, parasites, or fungi, to survive in the presence of a chemical drug that was previously effective in killing it or inhibiting its growth. The concept of drug resistance was first considered when bacteria became resistant to certain antibiotics, but since then similar mechanisms have been found to occur in other diseases; among many are cancer cells developing resistance to chemotherapy drugs and human immunodeficiency virus (HIV) becoming resistance to antiretroviral drugs.

The first true antibiotic, penicillin, was discovered by Alexander Fleming, Professor of Bacteriology at the St. Mary's Hospital in London in 1928. However, as early as 1908, Paul Ehrlich, the father of modern chemotherapy, had already observed the existence of stably inherited drug resistance in *Trypanosoma* (Ehrlich, 1909). Thus, antimicrobial resistance is not a new concept. Antimicrobial resistance was recognized even before the dawn of the antibiotic era. By the 1950s, the medical community was already aware of the problem of antimicrobial resistance. Notably, methicillin was first clinically used in 1959 and only 2 years later, scientists had already identified the first case of methicillin-resistant *Staphylococcus aureus* (Jevons, 1961). This demonstrated the short evolution cycle in the development of antimicrobial resistance in bacteria and other microorganisms.

Less than a century since the discovery of the first antibiotic, antimicrobial resistance has become one of the biggest threats to global health and human development. Many common pathogens are becoming resistant to the antibiotics resulting in longer illnesses and higher mortality. Concurrently, not enough new antimicrobial drugs are being developed to replace increasingly ineffective ones. In September 2016, a historical meeting of world leaders at the United Nations (UN) General Assembly was held to address the seriousness and scope of the situation and commit to fighting antimicrobial resistance together. Notably, this was only the fourth time in UN history that a health topic is discussed at the General Assembly (HIV, noncommunicable diseases, and Ebola were the others).

Definitions

Following the definition by Brauner *et al.* (2016), “resistance” describes the inheritable ability of microorganisms to grow at high concentrations of an antimicrobial agent by acquiring resistance mutations and is quantified by the minimum inhibitory concentration (MIC) of the particular agent. The genes that are involved in these mechanisms are collectively termed the resistome. However, microorganisms can also survive extensive antimicrobial treatments without acquiring resistance mutations. The terms “tolerance” and “persistence” distinguish these modes of survival from “resistance,” but the definitions of these different terms, and their distinction from one another, have remained somewhat ambiguous. “Tolerance” is more generally used to describe the ability of microorganisms to survive transient exposure to high concentrations of an antimicrobial agent without a change in the MIC, which is often achieved by slowing down an essential microbial process, such as growth or metabolism. Tolerance may be acquired through a genetic mutation or conferred by environmental conditions. Dormancy may be viewed as an extreme case of slow growth and low metabolism, and dormancy that leads to tolerance may also be termed “drug indifference.” For example, *Bacillus anthracis* and *Clostridium difficile* can form highly resistant endospores under unfavorable conditions. In contrast to resistance and tolerance, which are attributes of the whole bacterial populations, “persistence” is the ability of a subpopulation of a clonal bacterial population to survive exposure to high concentrations of an antimicrobial agent. Persistence is typically observed when the majority of the bacterial population is rapidly killed while a subpopulation persists for a much longer period of time, despite the population being clonal.

The joint initiative by the European Centre for Disease Prevention and Control and the Centers for Disease Control and Prevention defined multiple drug resistance (MDR) as antimicrobial resistance shown by a microorganism to at least one antimicrobial agent in three or more drug categories. Recognizing different degrees of MDR, the terms “extensively drug resistant (XDR)” and “pandrug-resistant (PDR)” have also been introduced (Magiorakos *et al.*, 2012). XDR is defined as nonsusceptibility to at least one antimicrobial agent in all but two or fewer drug categories (i.e., bacterial isolates remain susceptible to only one or two categories) and PDR refers to nonsusceptibility to all antimicrobial agents in all drug categories.

Molecular Mechanisms of Antimicrobial Resistance

The genetic characterization of antibiotic-resistant bacterial strains has uncovered many molecular mechanisms of resistance. The five fundamental mechanisms of antibiotic-resistance are (1) enzymatic activity that directly inactivate or degrade the antibiotic, (2) alteration of bacterial proteins that are targets of antibiotics, (3) reduction in membrane permeability to antibiotics, (4)

activation of efflux pumps that pump out antibiotics, and (5) activation of resistant bacterial metabolic pathways. Key candidate genes involved in the mechanisms of antibiotic-resistance are described in [Table 1](#).

Bacteria can destroy or modify antibiotics, thus resisting their action. Inactivation of antibiotics by hydrolysis is a major mechanism of antibiotic-resistance. Antibiotics can also be inactivated by transfer of chemical group. The addition of chemical groups to vulnerable sites on the antibiotic molecule by bacterial enzymes prevents the antibiotic from binding to its target protein as a result of steric hindrance. Various different chemical groups can be transferred, including acyl, phosphate, nucleotidyl, and ribitoyl groups, and the enzymes that are responsible form a large and diverse family of antibiotic-resistance enzymes.

Modification of the bacterial protein target is also an effective means of antibiotic resistance. Most antibiotics bind to the specific protein targets with high affinity, thus preventing the normal activity of the proteins. Changes to the protein structure that prevent efficient antibiotic binding, but still enable the protein to perform its normal function, can confer resistance to antibiotics.

Most antibiotics are targeted at intracellular processes, and must be able to penetrate the bacterial cell envelope to be effective. Compared to Gram-positive bacteria, Gram-negative bacteria are intrinsically less permeable to many antibiotics because of their outer membrane, which forms a permeability barrier. There are essentially two pathways by which antibiotics can penetrate the outer membrane: A lipid-mediated pathway for hydrophobic antibiotics, and general diffusion porins for hydrophilic antibiotics. The lipid and protein compositions of the outer membrane have a strong impact on the sensitivity of bacteria to many types of antibiotics, and drug resistance involving modifications of these macromolecules is common. The two major porin-based mechanisms for antibiotic-resistance are (1) reduction of porins or replacement of one or two major porins by another, and (2) altered function due to specific mutations reducing permeability.

Bacterial efflux pumps have physiological functions and their expression is tightly regulated in response to environmental and physiological triggers. Genes encoding for efflux pump proteins can be found on chromosomes or plasmids. Bacterial efflux pumps can be classified into five families based on their composition, number of transmembrane spanning regions, energy sources, and substrates. The five families are (1) resistance-nodulation-division (RND) family, (2) major facilitator superfamily (MFS), (3) ATP (adenosine triphosphate)-binding cassette (ABC) superfamily, (4) drug/metabolite transporter superfamily, and (5) multidrug and toxic compound extrusion family. The RND superfamily is only found in Gram-negative bacteria. On the other hand, efflux systems of the other four families are widely found in both Gram-positive and -negative bacteria. Bacterial efflux pumps actively transport many antibiotics out of the bacterial cell and are major contributors to the intrinsic resistance of bacteria. RND and MFS family pumps are associated extensively with clinically significant antibiotic resistance. When overexpressed, efflux pumps can also confer high levels of drug resistance to many clinically useful antibiotics. Some efflux pumps have narrow substrate specificity but many transport a wide range of structurally dissimilar substrates and are known as multidrug resistance efflux pumps. Our knowledge of MDR determinants are continuously propelled by the growing availability of the X-ray crystal structures of efflux pumps. These guide the development of novel efflux pump inhibitors that can potentially help in our war

Table 1 Key candidate genes involved in the mechanisms of antibiotic resistance

Mode of action	Class of antibiotics	Candidate genes	Mechanisms of resistance
Inhibition of protein synthesis	Macrolides	Erythromycin ribosome methylation genes (<i>erm</i>)	Posttranscriptional modifications of the <i>23SrRNA</i>
		Macrolide efflux genes (<i>mef</i>) <i>macA-macB</i> genes	Active drug efflux
		<i>23SrRNA</i> gene	Mutations of the 50S ribosomal subunit target
	Chloramphenicol	Chloramphenicol acetyltransferase gene (<i>cat</i>)	Elaboration of chloramphenicol acetyltransferase that inactivates chloramphenicol
		<i>23SrRNA</i> gene	Mutations of the 50S ribosomal subunit target
Interference with cell wall production	Aminoglycosides	Acriflavine resistance genes (<i>acr</i>)	Probable aminoglycoside efflux pump
		Aminoglycoside N(6')-acetyltransferase genes (<i>aacA</i>)	Aminoglycoside-modifying enzyme
	Tetracyclines	<i>16SrRNA</i> gene	Mutations of the 30S ribosomal subunit target
		Tetracycline resistance gene (<i>Tet</i>)	Active drug efflux
		β -lactamase structural genes (<i>bla</i>)	Inactivate the antibiotics by hydrolyzing the β -lactam ring
Interrupting nucleic acid synthesis	Fluoroquinolones	<i>mecA</i> gene	Alternative low-affinity penicillin-binding protein PBP2a
		DNA gyrase (<i>gyr</i>), DNA topoisomerase IV (<i>par</i>)	Mutations in target enzyme
	Rifampicin	DNA-dependent RNA polymerase B (<i>rpoB</i>)	Mutations in target enzyme
Blocking of DNA replication	Trimethoprim	<i>dfp</i> gene	Mutations of the target dihydrofolate reductase (DHFR)
		<i>folA</i> gene	Mutations of the structural gene for DHFR
	Sulfonamide (structural analogs of p-aminobenzoic acid)	Dihydropteroate synthase gene (<i>dhps</i>)	Mutations of the target dihydropteroate synthase
		Sulfonamide resistance genes (<i>sul</i>) <i>folP</i> gene	Resistant sulfonamide-resistant dihydropteroate synthase Mutations of the structural gene for DHPS

against antimicrobial resistance. In addition, preventing the overexpression of efflux genes by targeting to their transcription regulators is also an alternative emerging strategy to combat antimicrobial resistance.

Bacteria acquire resistant gene mutation and/or horizontal gene transfer via transformation, transduction, or conjugation. Antibiotic-resistance can be either plasmid-mediated or maintained on the bacterial chromosome. Many times, microorganisms employ several mechanisms in order to attain drug resistance.

Drug resistance among pathogenic fungal species, including *Candida*, *Aspergillus*, and *Cryptococcus*, generally involve similar mechanisms as antibiotic-resistance in bacteria. Reduced drug accumulation in fungal cells involve overexpression of efflux pumps as well as pH- and ATP-independent facilitated diffusion mechanisms. Efflux pumps in fungi mainly belong to the ABC superfamily and the MFS family. In addition, mutations in drug target genes may result in structural change of the fungal protein targets, thereby reducing the affinity of the inhibitors to their specific target. For example, mutations in *ERG11* (in *Candida albicans* and *Cryptococcus neoformans*) or *cyp51* (in *Aspergillus fumigatus*) that code for the ergosterol biosynthetic enzyme, lanosterol demethylase, change the structure of the enzyme, and decrease its affinity to specific antifungal drugs (Gonçalves *et al.*, 2016). Inhibition of ergosterol biosynthesis prevents the biosynthesis of ergosterol, which is a unique fungal cell membrane component, therefore the evoking the resistance mechanism. Another mechanism employed in resistant fungal strains is the overexpression of the drug target. Antifungal resistance can also be activated through stress response pathway regulation. For example, Hsp90 is a molecular chaperone that stabilizes the regulators in cellular stress responses. In response to drug inhibition, Hsp90 and other components of the pathway, including calcineurin and the Pkc1 signaling, are overexpressed (Robbins *et al.*, 2017).

Besides antimicrobial resistance, drug resistance also emerges in treatments of noninfectious human diseases. Drug resistance in cancer cells can also be observed. Besides playing a role in antimicrobial resistance, efflux pumps in cancer cells also act to reduce the accumulation of chemotherapeutic drugs in cancer cells. This often involves efflux pump proteins belonging to the ABC superfamily, which includes P-glycoprotein (P-gp), multidrug resistance protein 1, breast cancer resistance protein, and lung resistance-related protein. Anticancer drugs can also be inactivated by the enzymatic activity of glutathione S-transferase, which catalyzes the conjugation of glutathione to a xenobiotic compound by forming a thioether bond. Alterations in drug targets can also occur in drug-resistant cancer cells. Unlike normal cells, resistant tumor cells in breast cancer that lack estrogen receptors no longer depend on estrogen for growth. This leads to resistance to endocrine therapy. Decreased level of membrane permeability to chemotherapeutic drugs is demonstrated in the presence of lower levels of cholesterol and differences in lipid composition in cancer cells compared to normal cells.

In addition to the general mechanisms mentioned, cancer cells have also developed specific drug resistance mechanisms. Changes in the cell cycle may affect the balance between cell cycle arrest and apoptosis and disturbance to cell cycle checkpoints could lead to drug resistance. The activation of DNA damage checkpoint components allows the survival of cells after a drug treatment. Drug-resistant cancer cells may also evade apoptosis by enabling cell proliferation. Tumor suppressors in normal cells, such as p53, and phosphatase and tensin homolog deleted on chromosome 10, are defective in cancer cells, thereby disabling DNA damage repairs and cell cycle arrests. In addition to the defect in tumor suppressors, the overexpression of oncogenes, such as *Bcl-2* genes, may also inhibit apoptosis (Kartal-Yandim *et al.*, 2016).

The molecular mechanisms in antiviral resistance differ at different stages of viral infections. Mutations in genes coding for replication of viral DNA can decrease the affinity and binding of DNA polymerase to inhibitors, decrease the viral replication capacity, and affect hydrophobic interactions between nucleotides. Furthermore, antiviral drug resistance may also be caused by mutations in viral thymidine kinase encoding genes and lead to the decrease in phosphorylation of nucleoside analogs. It is because the phosphotransferase is used in antiviral therapies to produce competitive inhibitors for viral DNA polymerase. Mutations can also occur around active sites to prevent integrase and protease inhibitors from binding. Virus can also use different host cell coreceptors or the same coreceptors with changes in tropism, which may be the result of multiple mutations, to bypass the effects of inhibitors (Shafer *et al.*, 2011).

Bioinformatics in Combating Antimicrobial Resistance

Mutations introduce diversity into genomes, leading to selective changes and driving evolution. In particular, nonsynonymous single-nucleotide polymorphisms within the protein coding regions of the genome have been strongly associated with occurrence of drug resistance. Next-generation sequencing technologies have made the sequencing of whole-microbial genomes and metagenomes more affordable and have increased the feasibility of applying rapid whole-microbial genome sequencing in clinical microbiology laboratories. Furthermore, the number of microbial genomes and metagenomes deposited in the NCBI GenBank database has increased exponentially as more and more genomes are sequenced in a short time span. However, the barrier to the routine implementation of whole-genome sequencing is the lack of automated, user-friendly bioinformatics tools that interpret the sequence data and provide clinically meaningful information by scientists and clinicians. Several general databases are available to aid in rapidly identifying existing, putative, new, or emerging antibiotics resistance genes and mutations in chromosomal target genes that are associated with resistance. These include Antibiotic Resistance Genes Online (see "Relevant Website section"), the microbial database of protein toxins, virulence factors, and antibiotic-resistance genes for biodefense applications (see "Relevant Website section"), the Antibiotic Resistance Genes Database (see "Relevant Website section"), Resfinder database (see "Relevant Website section"), the Comprehensive Antibiotic Resistance Database (see "Relevant Website section"), the Antibiotic Resistance Gene-ANNOTation database (see "Relevant Website section"), the Resfams (see "Relevant Website section") and the MEGARes database (see "Relevant Website section"). In response to increasing concern over antimicrobial resistance, the team at Pathosystems Resource

Integration Center (PATRIC) has also developed new tools to facilitate researchers' understanding of the genetic basis of drug resistance (Antonopoulos *et al.*, 2017). The team used antimicrobial resistance phenotype data of more than 15,000 genomes in the PATRIC database to build machine learning-based classifiers that can predict the antimicrobial resistance phenotypes and the genomic regions associated with drug resistance that can be used for comparative analysis. Drug resistance databases for specific organisms, such as HIV and *Mycobacterium tuberculosis*, have also been developed. However, most research on bacterial antibiotic-resistance did not take into consideration gene–gene interactions and multiple genetic mutations in the emergence of transmissible drug resistance. Recently, a group of researchers from Huazhong Agricultural University (Wuhan, China) identified gene pairs associated with *Mycobacterium tuberculosis* drug resistance using GBOOST, a software package for identifying gene–gene interactions in genome-wide association studies (Cui *et al.*, 2016). GBOOST was used to detect SNP–SNP interactions on risk of drug resistance and a chi-square test method to examine the interaction effect between two SNPs and phenotypes. This method is also useful for providing a deeper insight into the mechanisms underlying drug resistance in other bacteria.

Cancer therapies are limited by the development of drug resistance, and mutations in drug targets are one of the main driving factors for the developing resistance to chemotherapeutic drugs. CancerDR is a cancer drug resistance database that will be useful for identification of genetic alterations in genes encoding drug targets, and in turn the residues responsible for drug resistance.

Systematic experimental evaluation of all genomic mutations and characterizing mutation effects of all mutations in a system of interest is impractically time-consuming and not cost-effective, even more so considering the range of different mechanisms in which mutations can affect protein function and interactions. Thus, this has created interest in the development of computational tools to understand the molecular consequences of mutations to aid and guide rational experimentation. These tools can also be employed to prioritize mutations for further experimental investigation, identification, and anticipation of resistant variants and resistance hotspots. Such knowledge can then be applied to the design of drugs less prone to resistance, as well as to drive the development of public health policies and aid in establishing more appropriate and personalized treatments. Computational methods, particularly homology modeling of the 3-dimensional structure of proteins, have been developed to understand the effects of coding mutations to protein function and interactions.

Currently, high-throughput screening (HTS) is widely used to screen large natural and artificial compound libraries against specific protein targets in drug discovery. However, this method can be costly and time-consuming even with the use of robotics. Computer-assisted or virtual screening (VS) can help to overcome some of the disadvantages of a full HTS when used to complement the HTS process in drug discovery. In the latter, VS is used to shortlist potential active compounds from large libraries, thus reducing the size of the library prior to the more costly and time-consuming HTS experiments. Unlike HTS experiments, VS simulations do not require the physical synthesis of compounds. However, VS still requires experimental information, such as protein structure for structure-based approach or binding properties of known active compounds for ligand-based approach. Molecular docking methodology is widely used in VS simulations in large part due to the efficiency of these calculations. In contrast to laboratory testing, molecular docking typically requires only a few minutes of computing time on a single core per ligand; thus, 10,000 to 100,000 compounds can be virtually screened on a small- to medium-sized cluster in a day. While molecular docking forms the basis for structure-based VS, the ligand-based approach is built upon the similarity principle in which similar compounds are assumed to cause similar biological effects. With this approach large ligand libraries can then be screened for compounds with similar chemical properties to the known actives, resulting in the identification of novel potentially active compounds. However, computer-assisted drug screening should still be a verified experimentally and VS is perhaps best used as an aid to HTS for prefiltering larger libraries to select subsets of compounds (focused library) to increase productivity in drug discovery.

Conclusion

The application of bioinformatics tools make it possible to practice precision medicine – the right medicine at the right dose for the right patient at the right time – in combating the drug resistance crisis by changing the way therapeutic drugs are developed and used to treat both infectious and noninfectious diseases, such as cancers.

Biographical Sketch

Mun Fai Loke obtained his PhD from the Department of Microbiology, Yong Loo Lin School of Medicine, National University of Singapore and his MBA from the University of Southern Queensland. He was a Senior Lecturer at the Department of Medical Microbiology, Faculty of Medicine, University of Malaya and a researcher with KK Women's and Children's Hospital. His main research interests are *Helicobacter pylori*, human gastrointestinal diseases, and rare genetic disorders.

Aimi Hanafi graduated with a master's degree from the Faculty of Medicine and Health Science, Universiti Putra Malaysia. Currently, she is a PhD student at the Department of Medical Microbiology, Faculty of Medicine, University of Malaya. Her PhD work focuses on the studying of antibiotic resistance mechanism and compensation in the human gastric pathogen, *Helicobacter pylori*.

Network-Based Analysis of Host-Pathogen Interactions

Introduction

Infectious diseases are defined as disorders caused by pathogenic microorganisms, such as bacteria, viruses, parasites or fungi that can be spread directly or indirectly (vector-borne) from one individual to another. Despite the rapid advances in treating infectious diseases over the last century, infectious diseases - such as pneumonia, flu, tuberculosis, HIV/AIDS, malaria etc. - continue to result in millions of deaths worldwide. As per the World Health Organization (WHO) and Center for Infectious Disease Research (CIDR) estimates, the mortality rates of many infectious diseases may have actually worsened over the past few decades; the infectious diseases therefore, remain a pressing concern for the public healthcare systems. The societal burden of such diseases have been further exacerbated by the emergence of new and more virulent strains of drug resistant pathogens; these events have, therefore, led to more and more research efforts to understand disease pathogenesis and to identify new candidate targets for more effective therapeutic intervention against infectious diseases. However, the strategies by which pathogens evade the host immune system and manipulate key host cellular processes for their survival remain to be fully elucidated and are, therefore, an impediment to the development of more effective therapeutics. Understanding the behaviour of the pathogen as it colonises its host and the emergent host behaviour when it comes into contact with the pathogen are, therefore, of prime interest for the researchers investigating the pathogenesis of infectious diseases.

Host-pathogen protein-protein interactions (PHIs) perform vital roles in the pathogenesis of infectious diseases. In the PHIs, the proteins encoded by the pathogenic genome invade the host cellular networks to subvert the host immune responses and to co-opt the host cellular machinery to colonise the host and spread the infection (Bhavsar *et al.*, 2007; Fig. 1). In response, host cells have evolved mechanisms to sense and clear out the pathogenic infection. This host-pathogen interplay can be highly competitive and often antagonistic in nature as the pathogens competitively disrupt the native PPIs and establish new ones with the host cellular factors. Therefore, the underlying organisational and functional structures of the PHI networks can be markedly different from those of the native host interactome (Franzosa and Xia, 2011). To understand the biology of pathogen infection, it is necessary to obtain a detailed understanding of how pathogenic proteins function inside the host cell, their interactions with the host cellular machinery and how these interactions impact cellular signalling pathways. Therefore, there is a pressing need for an integrative analysis of PHIs (Fels *et al.*, 2017; Ma-Lauer *et al.*, 2012).

The availability of complete genome sequences of many pathogens and their hosts, together with the rapid proliferation of omics technologies and the development of new experimental technologies that were more amenable to PPI mapping on a larger

Fig. 1 A schematic of host-pathogen interactions (PHIs).

scale, have made it easier to generate large scale PHI data for many different host-pathogen systems at different organisational levels. Systems-based approaches seek to integrate experimental data with bioinformatics tools for data analysis and modelling to generate new hypotheses and prioritise further experimental investigation; such approaches have emerged as ideal approaches to investigate the biology of PHIs, generate new hypotheses and prioritise targets for clinical therapies (Durmus *et al.*, 2015).

Significant amount of progress has been made in genome-wide mapping of PHIs for different pathogens (de Chassey *et al.*, 2008; Tripathi *et al.*, 2010; Uetz *et al.*, 2006; Brito and Pinney, 2017; Calderwood *et al.*, 2007; Friedel and Haas, 2011; de Chassey *et al.*, 2013a) and also there have been attempts to integrate interaction networks and 3D structural data to extract the general principles of PHIs (Franzosa and Xia, 2011). These studies have provided valuable insights into mechanisms of pathogenicity of different pathogens. Among the various pathogens, the maximum research effort has gone into systematic mapping of virus-human host interactions on a genome wide scale (Lum and Cristea, 2016); the low complexity of the viral genomes makes it relatively easier to map PHIs involving viral pathogens compared with PHIs involving pathogenic bacteria, fungi or eukaryotes.

In this review, we will discuss PHIs largely from the perspective of the viral pathogens of human diseases. We first discuss how experimentally defined PHI data have been utilised for understanding the infection and survival mechanisms of pathogens in their hosts. Next, we briefly outline the computational methods for large-scale PHI prediction and how they can help in highlighting useful PHIs and in knowledge discovery. Finally, we discuss the applications and likely future directions of PHI data analysis.

Experimental Methods to Determine PHIs on a Large Scale

Different experimental methods have been applied to identify cellular proteins interacting with pathogen proteins. These methods differ widely in their approach; they have their advantages and shortcomings and often provide coverage of the different aspects of PHIs. Yeast two-hybrid (Y2H) system and co-affinity purification are among the most frequently used and traditional technologies to experimentally characterise PHIs; these methodologies can be easily scaled to survey PHIs on a proteome-wide scale and it is, therefore, not surprising that they together have contributed over 90% of the publicly available PHI data (Gurimand *et al.*, 2015). In addition, protein arrays and protein-complementation assays are also being increasingly employed.

Y2H is an *in vivo* system based on the fact that a certain transcription factor (TF) can be divided into two separate domains, an activating domain (AD) and the DNA binding domain (DBD), and these two domains can still function together to drive transcription when they co-locate in close proximity. In Y2H, both the DBD and the AD are fused to two separate proteins, called the *bait* and *prey*. If the bait and prey proteins interact with each other, the DBD recognises a specific DNA sequence in a promoter region and the AD is recruited within the proximity; the reconstituted TF stimulates transcription by enabling the RNA polymerase II to transcribe the downstream reporter gene (Fields and Song, 1989). Hence, the bait and prey proteins form a bridge between the DBD and AD. The yeast strain is usually deficient in the components of the pathways for histidine biosynthesis. Therefore, by using HIS3 gene, which encodes for the protein Imidazoleglycerol-phosphate dehydratase that catalyses the sixth step in histidine biosynthesis, as a reporter for the transcriptional activation, *bait* and *prey* protein interactions are easily detected by monitoring yeast growth on culture dishes with a solid medium lacking histidine. Researchers can also construct a cDNA library instead of the prey-fused protein coding regions, and perform the screening of the binding partners from the cDNA library. Sometimes, whole cDNA library screening process is automated, thereby, permitting high-throughput analysis (Buckholz *et al.*, 1999).

Y2H system has many advantages. It does not require any specialised equipment, and it is cost-effective. PPIs can be easily detected by monitoring the transformed yeast growth. Moreover, Y2H screening is highly sensitive. Therefore, this system is suitable for detecting weak and transient interactions, which are often the most interesting in PHI-induced signalling cascades. Third, the interaction reflects *in vivo* status. Yeast is a eukaryote; therefore, it supports the correct folding of eukaryotic proteins, including post-translational modifications (PTMs). These advantages therefore, easily facilitate the characterisation of physiologically relevant PPIs; thus, Y2H has become the method of choice to characterise PHIs in many host-pathogen systems (Durmus *et al.*, 2015; de Chassey *et al.*, 2008; Uetz *et al.*, 2006; Tripathi *et al.*, 2013; Nicod *et al.*, 2017; Dolan *et al.*, 2013; Shapira *et al.*, 2009).

However, Y2H suffers from notable deficiencies. Since the assay is highly sensitive, the self-activation of transcription and reporter gene expression by *bait* protein in the absence of *prey* protein may commonly occur; thus, leading to the identification of false positive PPIs. Y2H may also fail to detect many physiologically relevant PPIs since the yeast cell environment is different from that of a mammalian cell. Therefore, some important post-translational aspects such as protein sub-cellular localisation and/or post-translational modifications (PTMs), which are often required for certain PPIs, may not be reflected within yeast. Y2H is also at a slight disadvantage when characterising PPIs involving extracellular proteins or membrane proteins, since the two-hybrid system requires the fusion proteins to be translocated to the yeast nucleus. Moreover, Y2H is optimised for binary protein interactions and some PPIs require correct folding as subunits of a large protein complex. To overcome such limitations, different variations of Y2H, such as the mammalian cell based two-hybrid assay (Luo *et al.*, 1997), the membrane anchored two-hybrid assay (Snider *et al.*, 2010), and the three-hybrid assay (Maruta *et al.*, 2016) have been developed. For example, the Y2H membrane protein system, which identifies PPIs involving integral membrane proteins and membrane-associated proteins in an *in vivo* setting at the cellular membrane, was used to identify novel host protein interactions for hepatitis C virus (HCV) Core and NS4B proteins (Tripathi *et al.*, 2010), nearly all of which were not characterised by previously by the high throughput screens for HCV-host interactions using the conventional Y2H approach (de Chassey *et al.*, 2008).

Affinity purification–mass spectrometry (AP-MS) is another method to identify PPIs on a large scale; the method involves biochemical purification of protein complexes from cells, followed by the mass spectrometric identification of the components of the purified protein complexes (Dunham *et al.*, 2012). Immuno-precipitation using specific antibodies is a classical method to purify target proteins from the cells under native conditions. Affinity purification system is also available to purify ectopically expressed proteins. After the purification of an endogenous protein or an ectopically expressed affinity-tagged target protein, the co-purified proteins that are associated with the target proteins are identified by mass-spectrometry analysis, resulting in the mapping of the PPIs of the target protein. This method is widely used to characterise protein complexes of target proteins due to the simplicity and sensitivity of the mass-spectrometry analysis. For instance, flaviviruses, a group of positive-strand RNA viruses generally induce intracellular membrane rearrangement and form an organelle like structure, called the “replication organelle” that facilitates efficient genomic replication. Replication organelle appears in close proximity to the endoplasmic reticulum and also serves as a shell that protects the viruses against various cellular stress responses and therefore, it allows for a persistent viral replication in the cytoplasm. In a specific study, the replication organelle was biochemically purified from JEV (Japanese encephalitis virus, a member of the flaviviridae) infected cells and subject to extensive mass-spectrometry analyses that identified many host factors, including ESCRT subunits, and ER membrane shaping proteins, innate immunity factors as the constituents of the replication organelle. Subsequent analysis by Y2H revealed binary interactions between some of these factors and viral non-structural proteins and the follow up siRNA depletion experiments further confirmed their essential roles in viral propagation (Tabata *et al.*, 2016). In another study, Jäger *et al.* (2011) employed AP-MS coupled with a quantitative scoring system to identify 497 high-confidence HIV-human PPIs.

To overcome non-specific detection of co-purified proteins, several two-step tandem affinity protein purification systems have been developed (Burckstummer *et al.*, 2006). This approach allows the preparation of a substantially pure target protein complex and reduces the background signals. The quantitative mass-spectrometry analysis also has been used to identify the contaminants (Trinkle-Mulcahy *et al.*, 2008). However, the method does not always capture the direct interactions between a target protein and its binding partners and reflects only steady-state interactions, and therefore, possibly missing weak and transient interactions.

Eventually, a combination of different methods will provide a more comprehensive map of protein interaction dynamics, since each method will likely lead to the exploration of a different aspect of PHI interactome.

PPI Network-Based Analysis of PHIs

Construction and analysis of PHI networks (PHINs) spanning extensive protein-protein interaction (PPI) maps between host and pathogen interactomes is a promising avenue to obtain a better understanding of the biological context of PHIs and to understand the pathogenesis of infectious diseases.

Network topology that is the connectivity of the proteins in a PPI network (PPIN) can often provide relevant insights into the biological functions of the proteins and their relative importance in a PPIN (Raman, 2010). Analyses of PHIN across different pathogen-host systems have revealed systematic trends in host-pathogen interaction networks. In specific studies that examined host-pathogen PPIs in the context of pathogenesis of infectious diseases, it was noted that viral and bacterial pathogens preferentially interacted with network ‘hubs’ and ‘bottlenecks’ in the human protein interactome (de Chassey *et al.*, 2008; Tripathi *et al.*, 2013; Dyer *et al.*, 2008). Network topological attributes can indeed guide the prioritisation and selection of candidates for experimental characterisation of pathogen-induced disorders (Tripathi *et al.*, 2012). For instance, Diamond *et al.* (2012) combined topological properties derived from a protein association network based on clinical data to evaluate the onset and acuteness of HCV-induced liver fibrosis and they identified a novel role of protein kinase A RII- α , which was judged to be a ‘bottleneck’ in the protein association network, to play a key role in HCV-induced liver injury (Diamond *et al.*, 2012).

Halehalli and Nagarajaram (2015) further established that in addition to targeting ‘hubs’ and ‘bottlenecks’, pathogenic proteins disproportionately form complexes with intrinsically disordered proteins and they proposed disorder associated conformational flexibility as one of the typical characteristics of VHIs (Halehalli and Nagarajaram, 2015).

PHIs Across Pathogenic Species

PHINs are also very useful in understanding the differences in strategies adopted by phylogenetically different pathogenic species to circumvent the host defence systems and modulate the host cellular machinery to survive in the intracellular environment and for their propagation during the infectious process. For instance, a comparison of PHI networks involving DNA and RNA viruses highlighted that while the DNA viruses simultaneously perturbed both the cellular and metabolic processes, RNA viruses preferentially targeted host factors associated with intracellular transport, translational machinery and sub-cellular localisation (Durmus and Ulgen, 2017). Among other examples, pathogenic bacteria also interact with host interactomes via different mechanisms and some of these mechanisms are remarkably different from those employed by pathogenic viruses (Nicod *et al.*, 2017). A key difference is that bacteria do not explicitly depend on the host cellular machinery for their own replication, since unlike viruses, bacteria have a living and a fully functional cellular machinery of their own. Therefore, a deeper understanding of the specifics of PHI networks involved in the infection by different classes of pathogenic organisms will facilitate a development of more specific and probably more effective therapeutics against infectious diseases.

Despite the rapid strides in the construction and analysis of PHINs, a more detailed and broad-based analysis is hampered by the limited amount of large-scale PHI data and the host PPI interactome data, especially in the case of animal model systems

(Murakami *et al.*, 2017) that are often used to investigate the pathogenesis of infectious human diseases. Therefore, it is necessary to deploy computational tools and approaches for literature mining and PHI prediction to maximise the availability of PHI and host PPI data and ensure the robustness of biological analyses leveraging PHINs (Table 1).

An example of such an approach would to leverage the principle of orthology in model organism research; this is based on the belief that the genetic makeup of the different cellular processes (such as PPIs) is inherently conserved across different organisms. Tripathi *et al.* (2012), for instance, analysed the biological significance of differential protein levels in transgenic mouse models of HCV infection. The differentially expressed mouse proteins were assimilated into an orthologous human protein interactome with the help of TargetMine data analysis platform (Chen *et al.*, 2011, 2016), to highlight the cellular pathways significantly impacted by HCV infection and to prioritise novel anti-HCV host factors. Follow-up cellular assays validated VTI1A, a vesicular transport associated factor, as a novel regulator of HCV propagation.

Extracting PHIs From Literature and Public Databases

PHIs are scattered across several published studies in the biomedical literature and many publicly available databases that catalogue different types of PHIs. For instance, virus–host interactions (VHIs) for a large number of viruses can be easily sourced from organism-specific resources such as Human Immunodeficiency Virus (HIV)-1 Human-Interaction Database (Fu *et al.*, 2009) or databases that are entirely dedicated to VHIs such as VirHostNet (Guirimand *et al.*, 2015), VirusMentha (Calderone *et al.*, 2015) and ViRBase (Li *et al.*, 2015). Likewise, PATRIC (Wattam *et al.*, 2014) is a resource that exclusively catalogues bacterial–host interactions. Additionally, there are comprehensive publicly available databases such as HPIDB (Ammari *et al.*, 2016), PHI-base (Urban *et al.*, 2017), PHIDIAS (Xiang *et al.*, 2007) and PHISTO (Durmus *et al.*, 2013) that offer a more generic repository of PHIs and occasionally tools to visualise and analyse PHI data. However, due to an ever increasing volume of the biomedical literature describing the pathogenesis of infectious diseases, the identification of specific PHIs and their roles in pathogenicity is a non-trivial task and therefore, it can be a while before many discoveries are reflected in the PHI databases. A vast amount of PHI data, thus, remains tucked away uncured in a large number of published studies; therefore, the recent years have witnessed a rapid development of computational methods for biomedical literature mining, especially in the context of PHIs (see below).

Some studies have used publicly available computational tools that facilitate the retrieval and extraction of relevant information from the biomedical literature such as PubMed to gather abstracts containing the relevant host and pathogen keywords as well as interaction verbs (including “interact”, “bind”, “attach”, “associate”). These steps were followed by a careful manual curation to extract pairwise PHIs to complement the experimentally determined PHIs (de Chassey *et al.*, 2008; Tripathi *et al.*, 2013). However, such methods are laborious, highly context-specific and difficult to employ on a larger scale and for extracting PHIs in general. To address the challenges of extracting PHIs from the literature, different methods using text mining have been employed to extract PHIs from the biomedical literature (Durmus *et al.*, 2015). These have included methods that focus on gathering and selecting literature abstracts that contain PHI-related information; Yin *et al.* (2010) were the first to report a machine learning-based automated text-mining system to identify research articles describing PHIs. Subsequently, Thieu *et al.* (2012) developed a hybrid procedure encompassing machine learning and language-based approaches to perform a more rigorous

Table 1 A selection of computational approaches for prediction and analysis of PHIs

S. No.	Method	Type of method	Pathogenic species	Reference
1.	Yin <i>et al.</i> – Document classification	Text-mining	All	Yin <i>et al.</i> (2010)
2.	Thieu <i>et al.</i> – Semantic analysis with machine learning and language processing	Text-mining	All	Thieu <i>et al.</i> (2012)
3.	Cui <i>et al.</i> – Protein sequence information	Machine learning using SVM classifier	Viruses	Cui <i>et al.</i> (2012)
4.	Dyer <i>et al.</i> – Protein domain profiles	Bayesian statistics	<i>Plasmodium falciparum</i>	Dyer <i>et al.</i> (2007)

semantic analysis of the biomedical literature to extract PHIs. The development of newer and more sophisticated methods that take into account the unique aspects of different PHIs (Karadeniz *et al.*, 2015) for PHI extraction from the biomedical literature will not only improve and the visibility and coverage of PHIs with the researchers and existing PHI repositories, but also complement PHIN-centric analyses to better understand the biology of pathogenesis.

In Silico Prediction of PHIs

Despite the increasing availability of experimentally defined PHIs, much of the available data provides only a partial coverage of all the probable PHIs and that too mostly for well-studied pathogens. The limited coverage of experimentally-determined PHIs is chiefly because these methods are resource-intensive and time consuming and thus, the construction of PHI interactomes using experimental methods is technically challenging. Therefore, it is of significant importance to develop new computational methods that can build inter-species PPI prediction models to prioritise the experimental scope and accelerate the discovery of PHIs (Nourani *et al.*, 2015; Halder *et al.*, 2017).

Many different approaches for *in silico* prediction of PHIs have been developed; they variously utilise protein sequence information (Cui *et al.*, 2012), protein domain profiles (Dyer *et al.*, 2007), protein structural properties and structural similarity (Franzosa and Xia, 2011; de Chassey *et al.*, 2013b) and principles of homology and “interologues” based on known PHIs (Coelho *et al.*, 2014) among others, using classical machine learning approaches. These “classical” methods work well enough where sufficient training data are available, but as often is the case with PHIs, there is a distinct scarcity of high-quality PHI data, especially for many less studied pathogens, and this problem contributes to a lack of sufficient PHI features for supervised machine learning (Kshirsagar *et al.*, 2012). More recently, methods that employ integrative genomics data and more sophisticated machine-learning frameworks, such as multitask learning that aims to simultaneously examine different related tasks (in this instance sufficiently related pathogenic diseases) and to extract common features and combine them into a predictive model, are becoming increasingly popular for predicting PHIs (Kshirsagar *et al.*, 2013).

However, the bulk of PHI prediction methods remain focused on species-specific PHIs. To name a few, Zhou *et al.* (2014) employed a homology-based approach to predict host-pathogen PPIs between human and a tuberculosis-causing bacterial pathogen *M. tuberculosis* and identified key properties of the host and pathogen proteins involved in these PPIs. Han *et al.* (2016) constructed a computationally predicted PPIN of *Bacillus licheniformis* and identified novel protein complexes and assigned functional annotations for previously uncharacterised proteins.

Conclusions

Studies on PHIs have observed common themes underlying the onset of various human diseases associated with pathogenic infection in humans, a better understanding of which may be helpful in optimising broad spectrum approaches to counteracting a wide range of pathogenic infections.

A deeper analysis and understanding of PHIs will considerably aid in the identification of new clinically relevant targets for optimising the therapeutic strategies to manipulate PHIs and thus, more effectively combat infectious diseases. Moreover, the genetic variability of pathogenic, especially viral genomes has facilitated the emergence of drug resistance against drugs that target pathogenic components. Therefore, antibacterials and antivirals that target less mutable host proteins that are critical to pathogenesis, preferably with minimal adverse side effects, may provide attractive alternatives to existing therapies. Additional studies on the evolution of PHIs along with the evolution of the pathogens and hosts themselves, should also contribute to developing better strategies for inhibiting PHIs for newer and better therapies.

Introduction

The earth formed about 4.5 billion years ago had no signs of life, until 1 billion years later, when Earth saw the emergence of life, the evidence of which can be found in fossils dating back to 3.5 billion years ago (Brasier *et al.*, 2006; Dalrymple, 2001; Dodd *et al.*, 2017; Mojzsis *et al.*, 1996; Schopf and Packer, 1987). Since then, life on earth has seen three major phases of evolution. The first was the appearance of prokaryotic organisms (single celled organism having undefined nucleus), then came eukaryotes (highly organized single cell with defined nucleus and chromosomes with an arranged DNA), and finally the evolution of multicellular organisms (combination of eukaryotic cells), which occurred mainly in the Precambrian period (Knoll, 2003, 2015; Schopf, 2001). Thus, evolution can be defined as a transition or adaptation of an organism, in response to the environmental conditions over the course of time. Evolution can be classified into three types: Chemical evolution (Oró, 1983), molecular evolution, and Darwinian evolution. Chemical evolution majorly denotes the prebiotic (before biology) formation of organic molecules in the period between the formation of the earth and the first appearance of a living cell. Molecular evolution refers to the changes in living systems that have occurred thereafter, eventually leading to the formation of unicellular and multicellular organisms. Darwinian evolution refers to the events after molecular evolution, which led to the speciation as seen today on Earth. Fig. 1 provides a schematic representation of the evolutionary changes that took place (Pattabhi and Gautham, 2002).

Stages of Evolution

Chemical Evolution (Prebiotic Earth)

The current understanding of the conditions on prebiotic Earth and the idea of gradual chemical evolution of life, otherwise known as abiogenesis (spontaneous generation), were put forth independently by Oparin and Haldane (see references in Fox, 1974).

Fig. 1 Beginning of life on Earth.

Spontaneous generation

Oparin and Haldane were the first ones to revive the idea of abiogenesis. Haldane, in particular, was fascinated with the experiments where organic molecules were formed from the mixture of H_2O , CO_2 , and NH_3 in the presence of ultraviolet light. Haldane further suggested that the strong reducing conditions may have been present at that time, which paved the way for the atmosphere of the early earth. Haldane's article in 1929 recommended that the earth's prebiotic soup would have formed first, after which organic mixes of simple sugars and amino acids came into being (Haldane, 1929). Oparin, on the other hand, stated that the primordial soup consisting of organic molecules could be created in an anaerobic atmosphere in the presence of sunlight, wherein the coacervate droplets would be formed as a result of the complex reaction undergone by the organic molecules (Oparin, 1924). These coacervate droplets would then merge with the neighbor droplets, and reproduce by the fission process (Fox, 1974). Inspired by the strong arguments of Oparin and Haldane, Stanley Miller, along with his graduate advisor Harold Urey, tested Oparin–Haldane's early earth hypothesis in 1953 (Miller, 1953; Miller and Urey, 1959).

Miller–Urey experiment

The Miller–Urey experiment established the capability of the earth's primitive atmosphere in building life from inorganic materials. It proved that the conditions existing in the earth's primitive atmosphere were sufficient enough to form organic molecules like amino acids. Their experimental steps consisted of (1) assemblage of a reducing atmosphere rich in hydrogen, and devoid of gaseous oxygen; (2) reducing atmospheres of H_2 over water at ocean's brim; (3) maintenance of H_2 and H_2O mixture below 100°C ; and (4) trigger lightning in the form of sparks.

In order to prove the hypothesis, they placed the molecules that may have been present at the early stages of the earth's time, like methane (CH_4), hydrogen (H_2), and ammonia (NH_3) gases into a moist locale above a water-containing flask (mock ocean of water). To mimic the primordial lightning, they used electrical current for the setup. A few days later, they could observe organic compounds in the flask, some of which were amino acids, the precursor of proteins. Using chromatographic techniques, they were able to confirm the presence of amino acids (glycine, alanine, aspartic acid, glutamic acid, β -alanine), purine and pyrimidines, and other organic compounds such as urea, lactic acid, glycolic acid, succinic acid, and propionic acid. The Miller–Urey experiment was able to successfully validate the emergence of biological molecules from the nonbiological substances (Miller, 1953; Miller and Urey, 1959) (Fig. 2).

Molecular Evolution (Complex Biological Molecules and Protocells)

Though Miller–Urey demonstrated the formation of simple biomolecules, the actual chemical evolution would depend upon the polymerization or condensation of these monomers into polymers (macromolecules like polypeptides, polysaccharides). For example, nucleic acid bases can be synthesized under prebiotic conditions (condensation of HCN and H_2O catalyzed by NH_3), while the sugars can be synthesized by the polymerization of formaldehyde (CH_2O) catalyzed by the divalent cations, alumina, or clay (Miller, 1953; Miller and Urey, 1959). But how these molecules organized themselves to form a cell was the next big question.

Sydney Fox and his team in the 1950s synthesized some peptidelike products by heating a dry mixture of amino acids at the temperature between 150 and 180°C , which they termed as proteinoids, meaning a thermal protein. Unlike the default linear

Fig. 2 Schematic representation of Miller–Urey's experiment.

proteins that are produced by the cell, proteinoids are highly branched polypeptides, exhibiting catalytic activity, and susceptibility to digestion by proteases, which are the properties shown only by the biological proteins (Fox *et al.*, 1959).

Origin of cells and organized structure

Macromolecules, due to their intermolecular forces, may have aggregated to form the membrane-enclosed droplets known as coacervates and microspheres, which exhibits features similar to that of a living system (selective permeability, and energy use). Coacervates (meaning “to assemble together or cluster”) are an agglomeration of colloidal particles in a liquid phase that stays in the form of minuscule droplets (Fig. 3). Coacervates display a number of compelling features:

- exchange substance with the environment,
- increases in size,
- selective concentration of the compounds within them (De Jong and Kruyt, 1929).

Oparin had earlier proposed that coacervates may have been the intermediate stage between loose molecules and living systems. He observed that droplets survived longer when they carried out polymerization reactions. Microscopic membrane-bound spheres (termed microspheres), however, are formed when proteinoids are boiled in water and cooled off. These microspheres are uniform in size, stable, and double membrane-bound, resembling a typical cell, and can multiply by fission and budding. They also present the properties of osmosis, growth in size, and selective absorption of chemicals, which are usually associated with normal cells. This spontaneous self-congregation of macromolecules into coacervates and microspheres is indicative of the fact that the contingency of similar structures under those primitive atmospheres may have probably led to the development of more organized and defined membrane-bound structure containing molecules, called protocells. Later, protocells may have been subjected to natural selection, which acted as a driving force in the origination of much more dominant and favorable molecules, and structures (Oparin, 2003).

Membrane defined the first cell

This idea was first proposed by Haldane (1929), saying that “the cell consists of numerous half-living chemical molecules suspended in water and enclosed in an oily film. When the whole sea was a vast chemical laboratory the conditions for the formation of such films must have been relatively favourable....”. Goldacre (1958) went on to suggest that the first cell membranes may be formed as a result of the wave-action behavior of the lipid-like surfactants. Bangham *et al.* (1965) were the first group to prove that phospholipids readily formed lipid-bilayer vesicles, called liposomes. The development of an outer membrane must have been the path-defining events leading to the formation of the first cell. The need for containment is generally attained by the amphipathic property of any molecule, where the molecule is semihydrophobic and semihydrophilic. When such a molecule is placed in water, they assemble, arranging their hydrophobic halves as close to one another away from water, while keeping their hydrophilic halves exposed to water. These amphipathic molecules readily gather to form bilayers, creating closed vesicles. Several studies have shown the production of the phospholipids using simulated prebiotic conditions from mixtures of fatty acids, glycerol, and phosphate (Hargreaves *et al.*, 1977; Rao *et al.*, 1982).

Majorly all the present-day cells are surrounded by plasma consisting of amphipathic molecules mainly the phospholipids. Hence, it can be assumed that the first membrane-bound cells were formed by the spontaneous assembly of phospholipids molecules from the prebiotic soup, enfolding a self-replicating mixture of RNA and other molecules within (Fig. 4). However, it is

Fig. 3 Coacervation process.

Fig. 4 Formation of the membrane enclosed first cell.

not clear as to when this happened. But, once the RNA molecules were enclosed inside a closed membrane, they may have begun to evolve into carriers of genetic instructions.

Current model for origin of life hypothesis

Many scientists have debated as to what came first – Was it RNA, proteins, or lipids? However, the hypotheses that have been proposed so far depend on the number of discoveries about the origin of molecular and cellular components of life; these are listed in the order of postulated emergence:

Clay hypothesis

The complexity of RNA makes it doubtful as to whether it can be produced nonbiologically or not. So scientists have suggested that some clays have properties to act as enhancers for the creation of the RNA world. This proposal saw very less support among the scientific community (Ferris, 1999). Researchers have demonstrated that clay (montmorillonite) has the ability to enhance the conversion of fatty acids to “bubbles,” which can encapsulate RNA. These bubbles then merge with nearby lipids, and then multiply. This proves that primitive cells may have been formed via similar process (Hanczyc *et al.*, 2003).

Lipid world

Many evolutionists believe that double-walled lipids may have set the initial basis of life on earth as these can readily form liposome structures, and reproduce (Garwood, 2012; Trevors and Psenner, 2001). Though they are devoid of any genetic information, but after passing through selection pressure points, RNA may have formed inside the liposome, thus giving way to the origin of life (Segré *et al.*, 2001).

Iron–sulfur world

A series of experiments successfully demonstrated that using sulfides (iron sulfide and nickel sulfide) as catalysts, one can produce proteins, amino acids from inorganic materials (CO, H₂S). The steps required were maintained at 100°C, with moderate pressures. This suggested that some of the self-sustaining protein may have been produced in the vicinity of hydrothermal vents (Wächtershäuser, 2000).

RNA world

This is the most widely accepted model to explain the initiation of life on Earth. The discovery of ribozymes puts forth that earlier life forms may have been entirely based on RNA. They held the view that RNA may have acted as both template and enzyme (ribozyme), and thus replicated on its own, thereby setting the foundations of life on Earth. This theory was further supported when cofactors, which often carry RNA nucleotides with them, were placed in the argued scenario (Orgel and Crick, 1993; Shapiro, 2007).

Though ribozymes like enzymes were produced in *in vitro* conditions, some were still doubtful of their reality in the early Earth time frame. Many came up with suggestions that there may have been a pre-RNA world before the RNA world, where the earliest ribozymes may have been formed of PNA (peptide nucleic acid), a simpler form of RNA (Böhler *et al.*, 1995; Nelson *et al.*, 2000;

Orgel, 2000). PNA was believed to have been composed of bases bound to a peptide-like backbone, with spontaneous polymerization capabilities. Later, it may have been replaced by RNA that has a sugar-phosphate backbone. They would also have had no speciation, but depended on selection points, and over the years, RNA was replaced by DNA (Hoenigsberg, 2003; Joyce, 2002; Trevors and Abel, 2004).

Another experimental proof to support this RNA theory was provided by Martin and Russell (2003). They proposed that precipitates of some porous metal sulfide can aid in the synthesis of RNA at oceanic pressures and the temperature of about 100°C near hydrothermal vents. This would mean that lipids may have been the last to appear among cell components.

Panspermia

Panspermia theory was first described by the chemist Arrhenius (1903). According to this theory, life arose somewhere in the universe, and these seeds of life (microbial spores) were brought to Earth probably by a meteor or comets. The astronomer duo, Fred Hoyle and Chandra Wickramasinghe, have actively propagated this theory after finding traces of biopolymer in the space dust. They stated that comets containing life forms inside entered the earth about 4 billion years ago, after which life began on earth 4.5 billion years ago. The dust from space has been reported to have all the features that are typical for a microbial occurrence (Hoyle and Wickramasinghe, 1977, 2000). They further believe that life forms have been continuously invading earth from outside, and are causing disease outbreaks and microevolution (Hoyle and Wickramasinghe, 1979). With the proof that the microbes can survive the ultraviolet exposure in space (Clancy *et al.*, 2005; Horneck *et al.*, 2010) and in meteorites (Kvenvolden *et al.*, 1970; McKay *et al.*, 1996), the presence of glycine in Sagittarius B2 (Kuan *et al.*, 2003) and its precursor, “methanimine” in Arp 220 (Salter *et al.*, 2008), the isolation of microbes *Bacillus simplex*, *Staphylococcus pasteurii*, and a fungus *Engyodontium album* via air sampling of the tropopause (Narlikar *et al.*, 2003; Wainwright *et al.*, 2002), and synthesis of DNA and RNA using the compounds found inside a meteorite (Callahan *et al.*, 2011), the panspermia theory has gained more acceptance among scientists. Most recent studies have detected anthracene, naphthalene 700 light-years from the sun, towards the star Cernis 52 (Iglesias-Groth *et al.*, 2008, 2010).

Darwinian Evolution

Darwin was an English naturalist who provided the world with the evidence for the scientific theory of evolution. He defined evolution as “descent with modification,” which states that all species have evolved over the time from a “common ancestor” through the process of natural selection. This theory of natural selection acting as a base point for evolution has been widely accepted by the scientific community, and now has become the basis of modern evolutionary theory.

Darwin’s trip on the *Beagle* and his study on finches led him to theorize the three main principles of evolution in his book *The Origin of Species* (Fig. 5): (1) variation in characters exists among individuals in a given population, (2) these variations can be inherited by the next generation, (3) some forms of inherited traits prove to be advantageous for some individual in terms of survival and reproduction rates than the others (Darwin, 1859, 1871; Darwin and Wallace, 1858). Although Darwin developed his theory of evolution without basics on the molecular basis of life, but even at the molecular level, Darwin’s principles can be observed. For example, when one molecule becomes divergent, giving many variations, such variations at the molecular level can

Fig. 5 Process of natural selection.

be induced by various kinds of mutations, genetic drift, etc. at the nucleotide level, which in turn can hamper the protein structure and its function (Hartwell *et al.*, 2014; Patthy, 2009). However, the diversification of the common ancestors to their new progenies are dependent not only upon the natural selection, but also on the mutational and genetic drift effects.

Homology and Development

Richard Owen introduced the term *homolog* in 1843, defining it as “the same organ in different animals under every variety of form and function.” He next defined analogs as a “part or organ in one animal which has the same function as another part or organ in a different animal” (Owen, 1848). Though Darwin never used the term homology, Huxley’s review of Darwin’s book *The Origin of Species* invoked homology as evidence of evolution (Huxley, 1860).

Evolution is directly associated with homology, which is the eventual result of synapomorphies. *Homologs* can be either paralogs or orthologs (Fig. 6), where *paralogs* are homologous sequences separated by a gene duplication event, and *orthologs* are homologous sequences separated by a speciation event (when one species diverges into two) (Fitch, 1970; Panchen, 1994).

Speciation

Speciation is an evolutionary process that gives rise to two or more new and distinct biological species as a result of lineage-splitting from ancestral population. This manifests upon the insufficiency of gene flow between sister populations that directs each population to become irreversibly committed to entirely different evolutionary descent. The primal causes of speciation: Natural selection, genetic drift, and mutation.

Natural selection

Darwin popularized the idea of natural selection stating that speciation was the direct impact of the prolonged action of natural selection upon them. It is a process of diversification in survival and reproduction rate of individuals due to variation in their phenotypes. Here, the organisms in a given population that best adapt to the environment increase in frequency compared to less adapted ones over a number of generations (Darwin, 1859, 1871; Darwin and Wallace, 1858).

Genetic Drift

Genetic drift, often called the Sewall Wright effect, after the individual who set forth the idea of hereditary float, is the adjustment in the recurrence of a previous gene variant (allele) in a populace because of impact of random sampling (Barton and Charlesworth, 1984; Masel, 2011). Drift can cause allele fixation in a population.

Once an allele is fixed, genetic drift ceases; the allele frequency cannot be changed unless another allele is brought into the populace by means of mutation or gene flow. Although both genetic drift and natural selection affect evolution, genetic drift operates randomly, while natural selection functions in a direction that ensures survival and reproductive fitness of that particular organism (Kimura, 1968). One of the best examples of genetic drift is a genetic bottleneck (Charlesworth, 2009).

Genetic bottleneck

This is an evolutionary event where a population reduces drastically to a smaller size as a result of environmental factors, like earthquakes, floods, fires, disease, or droughts, or human activities, like genocide. This causes reduction in the genetic diversity of

Fig. 6 Orthologs and paralogs.

Fig. 7 Bottleneck effect.

the small population, compared to its parent population (Fig. 7). This leads to certain alleles getting overexpressed in the survival population, while other alleles may get underexpressed, or are absent altogether. As a direct aftermath of genetic drift, inbreeding and homogeneity increase in these populations, giving rise to the occurrence of deleterious mutations. For example, antigenic shift of the influenza virus (Webster, 1999), diversification of hyperthermophilic *Pyrococcus* due to genetic drift and natural selection (Escobar-Páramo *et al.*, 2005), etc.

Mutation

Neither selective pressure nor genetic drift can operate in the absence of mutation, which is responsible for the genetic variation (Fig. 8). The randomness of mutation is the prerequisite for Darwinian evolution where changes in the heritable feature in an organism occur randomly, without the interference from the organism's environment. Cairns observed that *E. coli* genes mutated in a such a directed way that it enabled the bacterial population to survive in the different environmental situations (Cairns *et al.*, 1988). Mutations of the ancestral genes can lead to specific adaptations in an individual, which may or may not be beneficial. For example, alcohol dehydrogenases in yeasts that help them to consume accumulated alcohol (Thomson *et al.*, 2005), and gain of pathogenicity in some bacteria (Groisman and Ochman, 1997).

Common Ancestor

Darwin was the first to propose that all living beings on earth share a common descent, saying "Therefore, I should infer from analogy that probably all the organic beings which have ever lived on this earth have descended from some one primordial form, into which life was first breathed" (Darwin, 1859). The common ancestor gave rise to the "last universal common ancestor" (LUCA), which is used to denote the most current common ancestor of all life forms on earth that share a common descent. The last known LUCA was morphologically and metabolically diverse, temperature adaptive, contained an RNA genome, and is said to have lived during the Paleoproterozoic era (Glansdorff *et al.*, 2008), signifying that it was probably similar to extremophiles. Scientists have recently identified 355 genes from the LUCA, by comparing the genomes from archaea, bacteria, and eukaryotes, which constitute the three domain classifications of life (Weiss, 2001). This would mean that even before speciation into three domains of life, LUCA already consisted of the means of conducting complex processes such as transcription and translation, and may have later acquired important genes via horizontal transfer (Gogarten and Deamer, 2016).

Diving deep into the evidences of early forms

It has been reported that the prokaryotes were the earliest forms of life on earth after LUCA. They possessed a single nucleus, DNA, RNA, some proteins and enzymes, had membrane-bound cell walls, but no cell organelles, except for the presence of ribosomes. They were believed to have lived in aquatic environments around 3 billion to 1.5 billion years ago (Penny and Poole, 1999). Below, we discuss the proof of their existence in early earth durations.

Fig. 8 Effect of mutation in evolution.

Extremophiles

Extremophiles are unicellular microbes (bacteria and archaea) that thrive in extreme environments. Many of these belong to archaea, which are considered to be an ancient bridge between bacteria and eukarya. They can be thermophilic, hyperthermophilic, acidophilic, and alkalophilic, etc. They have been considered to be the closest link to the organism that evolved on the earth (Rampelotto 2010; Rothschild and Mancinelli, 2001).

Thermophiles are heat-loving microbes that grow above 45°C, while hyperthermophiles live beyond 110°C, preferably in between 80 and 121°C. They have been found in hot springs, hydrothermal vents, and the deep subsurface, etc. (Rampelotto 2010; Rothschild and Mancinelli, 2001). Many scientists believe that life on earth started from the hydrothermal vents in the form of thermophiles and hyperthermophiles, due to their ability to resist a wide range of temperature and anaerobic conditions (Li and Kusky, 2007). Wächtershäuser, the iron-sulfur theorist, had identified LUCA inside a black smoker (hydrothermal vent) in the Atlantic Ocean (Huber and Wächtershäuser, 1998). *Pyrococcus fumaris*, one of the highly heat resistant bacteria, which is able to reproduce at 113°C, was also found near the walls of black smokers (Postgate, 1994). Some of the hyperthermophiles studied by Lin *et al.* (2006) were found to have lived in hydrothermal vents in South Africa for about million of years without photosynthesis. *Arqueobacteria*, found near the ancient black smoker chimneys in China are known to live in temperature of about 400°C, depending mainly upon chemosynthesis to produce H₂S (Martin and Russell, 2003). A thermoalkalophilic bacteria, *Thermus brockianus* isolated by Thompson *et al.* (2003) shows catalase activity over wide pH, and temperature range of 6–10 and 30–94°C, respectively. All these instances thus provide strong reinforcement that life may have been indeed originated from the deep ocean beds.

Acidophiles thrive at a low pH, while alkalophiles live in higher pH environments. Though most of the organisms are mesophilic in nature within the pH range of 5–9, acidophiles and alkalophiles have specific adaptations that help them survive an extreme pH range. Acidic environments can be observed in places having geochemical activities, which include the generation of H₂S near in hydrothermal vents, hot springs, coal mine debris, etc. (Rampelotto 2010; Rothschild and Mancinelli, 2001). Alkalophiles can be found in places rich in carbonates, like soda lakes in Egypt, the Rift Valley of Africa, and the western US. Halophiles prefer living in regions that have a high level of salinity, like the Great Salt Lake (US). Hoover *et al.* (2003) identified a novel species of obligate anaerobic, haloalkalophilic spirochete, *Spirocheta Americana*, that prefers living in salty alkaline sediments of California's Mono Lake; it can survive within a temperature range of 10–44°C, salt concentration of 2%–12% (w/v), and pH range 8–10.5.

Another type of extremophile is psychrophiles, which live in extreme cold environments, like the Arctic and Antarctica regions, due to the adaptation of their protein structures to the cold climate. The high amount of glycine in their structure help retain flexibility, while the low amount of charged and hydrophobic amino acids help reduce their inter/intra molecular interactions and allows the protein core to be smaller, in order to avoid freezing (Rampelotto 2010; Rothschild and Mancinelli, 2001). Christner *et al.* (2014) have found some archaean species in West Antarctic Ice Sheet that depended solely on NH₄⁺ and CH₄ for survival, and have been doing so for millions of years in total absence of sunlight or wind. Cryptoendoliths, also known as endoliths, in

particular, survive in the microscopic spaces deep within the rocks, aquifers, and fissures, deriving nutrients via chemosynthesis (Ehrenfreund *et al.*, 2001; Wynn-Williams *et al.*, 2001). These arouse high interest among astrobiologists who theorize that the endolithic regions of Mars and other planets may harbor these organisms. Endoliths have been reported to exist in the permafrost regions of Antarctica (José *et al.*, 2003), the Alps (Horath and Bachofen, 2009), the basalt from the Atlantic, Indian, and Pacific oceans (Lysnes *et al.*, 2004), and the Rocky Mountains (Walker *et al.*, 2005). Radioresistant bacteria are able to resist high levels of radiation (ionizing and nuclear). *Deinococcus radiodurans* can withstand radiation up to 5000 Gy (Gy), with no viability loss. Their radioresistance evolved due to the prolonged cellular desiccation (Mattimore and Battista, 1996). They can survive extreme cold, dehydration, vacuum, and acid, thus are known as a polyextremophile (Anderson, 1956). *D. geothermalis* can resist higher concentrations of gamma radiation, and thrives well in nuclear plants (Ferreira *et al.*, 1997).

Historical Proofs and Scientific Evidences of Early Evolution of Life

Evolution study requires a huge dedication in estimating the most likely number of possible mutations, and the probable elements that factor them. Since the evolution has already occurred, and there is no other means of witnessing these events, so the only way to understand them is to study historical evidence that has been the result of those journeys.

Evolution of Glucocorticoid Receptor

The glucocorticoid receptor (GR) is a known cellular receptor for glucocorticoids (GCs) (cortisol and corticosterone), which are a stress hormone. GCs are used in the treatment of various immune diseases, and this efficacy of the treatment is wholly dependent upon one's sensitivity towards GCs due to the variations in the GR protein that are governed by the GR gene. This particular protein, GR, would not have reached its present-day target function, had it not gone through the two most unlikely permissive mutations in the first place. Though these mutations didn't affect the functional aspect of the protein, they made sure that the protein gained tolerance towards later mutations, so that its sensitivity towards cortisol could be achieved (Carroll *et al.*, 2011; Harms and Thornton, 2014; Orlund *et al.*, 2007).

Harms and Thornton (2010) were able to resurrect the ancestral gene of GR (precursor of modern-day GR and mineralocorticoid (MR) receptors), which existed 450 million years ago, before it evolved its capacity to specifically recognize cortisol. They were able to identify two historical mutations that led to the evolution of GR's specificity. These mutations altered few crucial residues to create novel intermolecular (protein-ligand) and intramolecular contacts. The permissive effect of the mutation helped stabilize the specific section of the receptor, without obstructing protein structure, which in turn allowed it to endure the later function-switching mutations, thus defining the GR's sensitivity towards GC's reaction. Scientists have explored many other alternate theories, but none of them could explain the evolution of GR's sensitivity towards cortisol, except this one.

Evolution of Biological Carbon Fixation

The early ancestors of cyanobacteria are believed to be the ones to start the carbon fixation. When they first evolved their process of photosynthesis, water (H₂O) was used as the electron donor source in the etc pathway for the generation of ATP molecules, as a result of which the autotrophy came into being. However, this ability of cyanobacteria to use water as an electron source created the radical oxygenation of the atmosphere/environment, thereby leading to the large amount of CO₂ consumption (Brasier *et al.*, 2006; Kopp *et al.*, 2005; Tomitani *et al.*, 2006).

There are six known CO₂ fixation pathways that have functional overlaps, but their evolutionary journey and diversification from the parent pathway was not understood well before. It was Braakman and Smith (2012) whose study shed light into this complex diversification. They mapped the evolutionary journey of biological carbon fixation using the metabolic and parsimony-built phylogenetic data analysis, which traced all the modern pathways to a single parent pathway. It was remarked that this diversification was one of the earliest divergences in the tree of life that occurred solely due to the physicochemical changes (energy optimization and oxygen toxicity) in that particular environment. The root of the parsimony-generated phylogenetic tree was observed to be the combination two subnetwork pathway (reductive citric acid cycle and the Wood-Ljungdahl pathway) coalescing into a single network. These trees combine into a single connected network, one being the reductive citric acid cycle and the other being the Wood-Ljungdahl pathway, which is a linear folate-based pathway of the CO₂ reduction pathway. Though these selection pressures cannot be observed in the modern pathways, these were responsible for the primitive diversification of the ancestral carbon fixation.

The Origins of Fermentation, Evolution of Alcohol Dehydrogenases

Alcohol dehydrogenases (Adh) are crucial to the fermentation process, which converts pyruvate to ethanol forming acetaldehyde in between. Yeast was the first organism to have evolved this enzyme, wherein they convert sugars into alcohol using Adh1, and then later consume the accumulated alcohol using Adh2 enzyme, a homolog of Adh1 differing by 24 amino acids. However, research shows that the primitive form of Adh had the ability to only produce alcohol, and not consume them

Fig. 9 Phylogenetic tree of contemporary organisms.

(Danielsson and Jönvall, 1992; Gutheil *et al.*, 1992; Persson *et al.*, 2008). Thomson *et al.* (2005) used paleobiochemistry techniques to isolate AdhA, the last common ancestor of both Adh (Adh1 and Adh2) to identify the reason behind this variation. They found that the Adh_A was optimized to only produce alcohol from sugars and recycle the NADH generated from glycolysis. Excess production of alcohol helped yeasts eliminate their competitors, but as the earth evolved, the Cretaceous age brought upon the existence of fleshy fruits. Since fruits contain high amount of alcohols, especially rotting fruits, silent nucleotide dating proposed that yeasts needed a way to metabolize these exogenous alcohols, hence duplicated of Adh into Adh1 and Adh2.

Adaptations of Aromatases in Pigs

Aromatases are cytochrome P450-dependent enzymes that catalyze the conversion of an androgenic steroid (such as testosterone) to an estrogenic steroid (such as estradiol). The protein existed much before the emergence of fish and tetrapods (Callard *et al.*, 1984). Researchers have reported many aromatase genes to date. Teleost fish have two aromatase genes (Callard and Tchoudakova, 1997; Chang *et al.*, 1997), while cattle possess both a functional gene and a pseudogene (Fürbaß and Vanselow, 1995; Hinchelwood *et al.*, 1993). The majority of mammals have only one aromatase gene that codes for the aromatase enzyme through alternative splicing (Boerboom *et al.*, 1997; Delarue *et al.*, 1996, 1998; Harada, 1988; Hickey *et al.*, 1990; Terashima *et al.*, 1991; Simpson *et al.*, 1997).

However, pigs (*Sus scrofa*) have been reported to have three different mRNAs for aromatases (Callard and Tchoudakova, 1997; Choi *et al.*, 1996, 1997a,b; Corbin *et al.*, 1995; Conley *et al.*, 1997). Evidence suggests that these three aromatase gene variants were the result of gene duplication events, which occurred recently in the geologic time scale (Corbin *et al.*, 2004; Graddy *et al.*, 2000). The speculations identifying the functional aspects of these paralogs depend upon the order in which the gene duplication took place. For example, the recent events may have helped domestication of the pigs.

Adaptations of the Elongation Factors

The physical environment to which an ancestral organism may have been exposed can be speculated by resurrecting the protein of that particular organism in *in vitro* conditions, and then study its properties (Adey *et al.*, 1994; Chandrasekharan *et al.*, 1996; Chang *et al.*, 2002; Golding and Dean, 1998; Jermann *et al.*, 1995; Malcolm *et al.*, 1990; Miyazaki *et al.*, 2001). Researchers have been able to revive the protein sequences for Tu family (EF-Tu), the elongation factors that existed in ancient bacteria, and estimated their properties with respect to temperature. The ancient EF-Tu proteins were observed to be functional at the optimal temperature of 55–65°C, which indicates that they were thermophilic in nature, and not hyperthermophilic or mesophilic. This result can be thoroughly corroborated from the dispersion of thermophiles in the bacterial ancestries (Hugenholtz *et al.*, 1998), the G + C content of ancient rRNAs (Galtier *et al.*, 1999), and the geographical record of the molecular clocks (Cavalier-Smith, 2002).

Fig. 11 Elements of a typical phylogram.

Researchers have made use of paleobiochemistry techniques and phylogenetic analysis between many such microorganisms to investigate more about their ancestors.

Tracing the Evolutionary Steps Using Phylogeny

Phylogeny can be described as the relationship between all the organisms on Earth that have descended from a common ancestor, whether they are extinct or extant. Phylogenetics is the science of studying the evolutionary relatedness among biological groups and a phylogenetic tree is used to graphically represent this evolutionary relation related to the species of interest (Figs. 9–11).

More specialized phylogenetic methods have been developed now to meet specific needs, such as species and molecular phylogenetic tests, biogeographic hypotheses, testing, for evaluating amino acids of extinct or extant proteins, establish disease epidemiology and evolution, and even in forensic studies (Linder and Warnow, 2005).

Conclusion

The evolution traces the journey of life on Earth from water to land and air, from an ill-defined membrane-bound cell to modern day multicellular, complex organism over the vast layers of time and generations. With each step of evolution, distinct characters emerged following speciation; some retained their previous features, some developed new sets of traits making contemporary humans curious to understand these changes.

In this encyclopedic article, we have studied the different stages, theories, and evidences of evolution. We shed light on the forces responsible for the genetic variations and speciation. We have also discussed some of the specific adaptations undergone by some of the genes/characters and how these adaptations proved to be beneficial in shaping their survival. Last, but not the least, we have also vaguely touched upon the topic of phylogeny using which the phylogenetic relatedness of any organism can be traced.

Biographical Sketch

Himakshi Sarma is a PhD scholar at Molecular Modelling and Simulation Laboratory, Department of Molecular Biology and Biotechnology, Tezpur University, Assam, India. She has done her Post Graduation in Biotechnology from NEHU, Shillong, Meghalaya, in the year 2014. She is expertise on molecular dynamics (MD) simulation of biomolecules, molecular docking, virtual screening, drug designing and in silico alanine scanning mutagenesis (ASM). She is presently working on in silico modeling of Lemur tyrosine kinase (LMTK3), which is a protein kinase implicated in breast cancer progression and metastasis, using modeling and simulation approach.

Sushmita Pradhan is a PhD research scholar at the Molecular Modelling and Simulation Laboratory, Department of Molecular Biology and Biotechnology, Tezpur University, Tezpur, Assam since 2016. She completed her Masters in Microbiology from Bangalore University in the year 2015. She has strong hands on analyzing the biomolecules using on molecular dynamics (MD) simulation, molecular docking, free energy analysis, mutational approaches, etc. She is currently working on Xeroderma pigmentosum A (XPA) protein, functions as the scaffold protein in nucleotide excision repair (NER).

Sandeep Kaushik is a passionate computational biologist with a wide exposure of computational approaches. Presently, he is carrying out his research as an Assistant Researcher (equivalent to Assistant Professor) at 3B's Research Group, University of Minho, Portugal. He has a PhD in Bioinformatics from National Institute of Immunology, New Delhi, India. He has a wide exposure on analysis of scientific data ranging from transcriptomic data on mycobacterial and human samples to genomic data from wheat. His research experience and expertise entails molecular dynamics simulations, RNA-sequencing data analysis using Bioconductor (R language based package), de novo genome assembly using various software like AbySS, automated protein prediction and annotation, database mining, agent-based modeling, and simulations. He has a cumulative experience of more than 10 years of programming using PERL, R language, and NetLogo. He has published his research in reputed international journals like *Molecular Cell*, *Biomaterials*, *Biophysical Journal*, and others. Currently, his research interest involves in silico modeling of disease conditions like breast cancer, using agent-based modeling and simulations approach.

M. V. Satish Kumar received a PhD in Biotechnology from Indian Institute of Technology Guwahati, Assam, India in 2010. From 2010 to 2012, he was with the Centre for Condensed Matter Theory (CCMT), Department of Physics, Indian Institute of Science Bangalore, India. He is currently working as Assistant Professor in the Department of Molecular Biology and Biotechnology, School of Sciences, Tezpur University, Assam, India. His research interests include understanding the functioning of intrinsically disordered proteins (IDPs), pathways of protein aggregation mechanism in neurodegenerative diseases like Alzheimer, Parkinson, etc., and also the features of protein–RNA interactions using computational techniques.

Inference of Horizontal Gene Transfer: Gaining Insights Into Evolution via Lateral Acquisition of Genetic Material

Suhaila Sulaiman, Nur S Yusoff, Ng S Mun, Haslina Makmur, and Mohd Firdaus-Raih, Universiti Kebangsaan Malaysia, Bangi, Malaysia

Introduction

Horizontal gene transfer (HGT) is defined as the movement of genetic materials between distantly related organisms (Crisp *et al.*, 2015). HGT is also referred to as lateral gene transfer. It was first reported in 1928 by Frederick Griffith, who demonstrated the uptake of foreign DNA through transformation in bacteria (Griffith, 1928). HGT has been shown to take place in both prokaryotes and eukaryotes although its mechanisms are more extensively studied for prokaryotes (Huang, 2013; Zhaxybayeva and Doolittle, 2011). Popa and Dagan (2011) reported that almost 75% of total genes in a microbial genome are the results of HGT events. In microbes, HGT may occur via three classical mechanisms: (i) Transformation (the uptake of nucleic acids), (ii) transduction (virus-mediated gene transfer) or (iii) conjugation (plasmid-mediated gene transfer).

Detection of HGT requires the separation of vertical and horizontal arrangements in a genome of interest. Vertical transfer involves a time-consuming transfer of genetic material from parents to progenies. On the other hand, horizontal transfer usually happens between individuals that are not in parent-progenies relationships; thus, it influences the genome diversity and evolution of a species. A process named amelioration usually occurs that ensures the horizontally acquired gene is beneficial to the new host. Thus, the acquired regions will be less apparent from their original hosts and amended according to new host genome (Lawrence and Ochman, 1997). Normally the acquired gene will ameliorate due to spontaneous mutations, ecological adaptation and interactions with environment (Gyles and Boerlin, 2014). This process makes the detection between closest relatives laborious, due to the similarities in genetic content and phylogeny (Adato *et al.*, 2015).

HGT often contributes to new functions and phenotypic variations such as adaptations to changing environments (Gyles and Boerlin, 2014; Yue *et al.*, 2012) or variations in pathogenicity and antibiotic resistance (Juhas, 2015; McElroy *et al.*, 2014). Cases of HGT in eukaryotes are reportedly associated with many modifying traits (Keeling and Palmer, 2008). Besides parasitic plants, HGT encompasses a huge range of autotrophic lineages (Keeling and Palmer, 2008; Sanchez-Puerta, 2014), bryophytes (Yue *et al.*, 2012), ferns (Davis *et al.*, 2005), basal angiosperms (Berghorsson *et al.*, 2004) and grasses (Christin *et al.*, 2012). It is hypothesized that the number of horizontally transferred genes correlates with increasing heterotrophic dependence (Yang *et al.*, 2016).

Three approaches are widely implemented in HGT detection based on best pair-wise alignment (BLAST) matches, sequence composition, or phylogenetic analysis (Zhaxybayeva, 2009). The composition of the sequence is one of the earliest ways to detect the HGT event and is done by assessing the bias of synonymous codons in the recipient genome (Lawrence and Ochman, 1997). Besides assessing the discrepancy of genome composition, analyzing phylogenetic relationships is also a commonly used practice to identify horizontally transferred genes; where gene phylogenies that diverge from the organism's own known lineage is an indication of the presence of HGT events (Keeling and Palmer, 2008).

In this article, we review and compare several approaches for HGT detection in bacteria and parasitic plant systems. Due to the diverse complexity of genome composition, determining a pipeline for HGT detection remains challenging.

Background

HGT Events

HGT is the transfer of genetic information from one organism to another where the transferred material can be between related organisms within the same kingdom or even between different kingdoms.

Intra-kingdom (prokaryote to prokaryote; eukaryote to eukaryote)

HGT is more common in prokaryotes due to its asexual reproduction and simpler cell organization. Other than gaining drug resistance, HGT rescues prokaryotes from irreversible deleterious mutations (Muller's ratchet) to maintain the genomic information (Takeuchi *et al.*, 2014). Mechanisms on how HGT occur in prokaryotes are clearer compared to in eukaryotes because the passing of genetic information in eukaryotes is mainly via vertical gene transfer. HGT events that occur between eukaryotes are more complex and can be of different combinations: between unicellular eukaryotes, between multicellular eukaryotes, between unicellular and multicellular eukaryotes, and within the eukaryote that is between the organellar genome and the nuclear genome (Blanchard and Lynch, 2000; Keeling and Palmer, 2008; Richardson and Palmer, 2007).

Inter-kingdom (prokaryote to eukaryote; eukaryote to prokaryote)

Inter-kingdom HGT is highly interesting because it occurs between distant organisms. The most common direction of inter-kingdom HGT is the transfer of genetic material from prokaryotes to eukaryotes. The fact that there are larger populations of

prokaryotes compared to eukaryotes in nature tend to make eukaryotes the gene recipients instead of the donor (Keeling and Palmer, 2008). Normally, eukaryotes gain prokaryotic genes mainly for adaptive evolution (Husnik and McCutcheon, 2017; Lacroix and Citovsky, 2016). Eukaryote-to-prokaryote transfer events are rare; however, the receipt of eukaryotic genes by prokaryotes has been reported as a means environmental adaptation (Sieber *et al.*, 2017) and for the general improvement of functions in prokaryotic systems (Koonin *et al.*, 2001).

HGT Detection

The surrogate and comparative methods are commonly used to study HGT (Ravenhall *et al.*, 2015) and is also applicable in eukaryotes (Jaron *et al.*, 2014). The surrogate or parametric method investigates the nucleotide base composition of the DNA sequence of interest (Jaron *et al.*, 2014). This method is extremely useful before the advent of next-generation sequencing technologies, and is able to depend only on the genome of interest to infer HGT events (Ravenhall *et al.*, 2015). In contrast, the comparative approach requires prior knowledge of a genome, which utilises phylogenetic identification for input genes or local alignment comparisons against a reference sequence database (Jaron *et al.*, 2014). All-against-all BLASTP searches are carried out to identify sequences with high similarities. Genes with BLAST hits to organisms distant from its close relatives and having relevance to the host are considered as horizontally derived ones. Over the years, many methods have been developed to detect HGT at the genome level. It is believed that by combining predictions from parametric and comparative methods, a more complete set of putative horizontally acquired genes can be retrieved (Ravenhall *et al.*, 2015).

Computational Analysis of HGT Genes

Traditionally, attention was given to a single genome of interest to study HGT events. As a result, only a handful of HGT events were identified due to the limitation of available data. With genome sequencing becoming more common and less cost prohibitive, the acquisition of genome sequences need no longer be limited to a single representative strain or individual as a species representative. This allows for the full complement of genes in a taxonomy to be represented by a pan-genome (Tettelin *et al.*, 2005).

However, in some cases where there is no genome sequence available, transcriptome data exploration is an alternative approach to discover the HGTs. This is applicable especially for larger organisms such as eukaryotes (plants and fungi) that are more costly to sequence the genomes compared to smaller genomes like bacteria and viruses. Here, we discuss the identification of HGT genes in bacterial genomes via pan-genome analysis (Fig. 1) and in plants via transcriptome profiling. A list of the computational tools that are discussed in this article is presented in Table 1.

Pan-Genome Informatics

Annotated genome sequences for organisms of interest are required to study HGT events via pan-genome analysis. Many approaches are taken to first annotate the genome sequences, and these may depend on several factors including computational capacities, genome size, type of organism and project strategic planning. For instance, The National Center for Biotechnology Information (NCBI) uses the Prokaryotic Genome Annotation Pipeline (PGAP) and the Eukaryotic Genome Annotation Pipeline (EGAP) for annotating prokaryote and eukaryote genomes, respectively. They are supported by the high performance computing cluster that enable the implementation of both pipelines containing many integrated analysis tools. On the other hand, other researchers with less capacity of computational resources show different implementation of genome annotation based on their customised approaches (Firdaus-Raih *et al.*, 2018; Noor *et al.*, 2014).

Although various genome annotation methods are in use, the mutual goal is still to derive as much information from the genome sequence as possible. The availability of annotated complete genomes enable the pan-genome analysis for an organism; this allows for the sets of core and variable genes from the organism's gene pool to be determined. The core genes refers to genes that are present in all organisms in the taxonomy and normally consist of housekeeping genes that are responsible for main phenotypic traits (Tettelin *et al.*, 2005). In contrast, the variable genes, also known as dispensable genes, are those that are present in some of the organisms (two or more strains) and typically involve functions such as virulence mechanisms, ecological adaptation and survival in different environments (Jeong *et al.*, 2017; Medini *et al.*, 2005).

Compiling the pan-genome can be done using several tools including EDGAR (Blom *et al.*, 2009), PGAT (Brittnacher *et al.*, 2011), PanGP (Zhao *et al.*, 2012) and Panseq (Xiao *et al.*, 2015) (Table 1). The resulting orthologous clusters can then be used to identify genes that are possibly involved in HGT events. On top of the catalogue of entire genes in the organism, more analysis can be performed to enrich the information, thus consolidation of these data will converge into a holistic understanding of the entire organism.

Atypical sequence signatures

Deviation of a gene's sequence composition signature, such as GC content, from the mean can be indicative of its origins from a foreign genome (Garcia-Vallvé *et al.*, 2000). Thus, the prediction of HGT gene candidates can be inferred with lower or higher GC content than the mean of the genome's GC content (Liu *et al.*, 2009). Many tools were developed to analyze the GC content of genes and genomes, such as EMBOSS geecee which calculates the percentage of GC (Rice *et al.*, 2000), GC-Profile which analyses

Fig. 1 Approaches in analysis of HGT using pan-genome data. The availability of genome data allows for a series of investigations via pan-genome analysis that can lead to the identification of horizontally transferred genes within the organism.

GC content by segmenting the genome (Gao and Zhang, 2006), and Artemis which allows for visualization of both the GC percentage and its deviation (Carver *et al.*, 2008).

Identification of genomic islands (GIs)

Genomic islands (GIs) refer to discrete DNA segments that establish horizontally transferred genes in a population (Jaron *et al.*, 2014). This region may integrate into the chromosome of the host; excised and transferred to a new host by transformation, conjugation or transduction. Proteins encoded within this region possibly present new functions in the recipient organism (Casacuberta and González, 2013). The prediction of GIs in prokaryotes can be better carried out than in eukaryotes due to the complexity of eukaryotic genomes. Many tools were developed to predict the occurrence of GIs in prokaryotic genomes such as GIPSy (Soares *et al.*, 2015), Zisland Explorer (Wei *et al.*, 2017) and IslandViewer 4 (Bertelli *et al.*, 2017). A good practice in predicting GIs is by consolidating the prediction outcomes from different tools by taking into account the different approaches that each tool implements to solve the problem.

In the most widely used software, IslandViewer 4, the prediction of GIs can be carried out using pre-computed genomes (complete bacterial and archaeal genomes from NCBI) or by uploading a genome sequence in EMBL or GENBANK format. This software incorporates four high precision prediction methods: IslandPick (Langille *et al.*, 2008), IslandPath-DIMOB (Hsiao *et al.*, 2003, 2005; Langille *et al.*, 2008), SIGI-HMM (Waack *et al.*, 2006), and Islander (Hudson *et al.*, 2015). The implementation of multiple prediction tools is important to ensure precise results and to reduce false positives in the predictions.

Predicting accurate GI boundaries is essential to obtain precise GI regions in the genome. This can be achieved by using IslandPick via comparative genomics approach if a reference genome is available (Langille *et al.*, 2008). Otherwise, Islander is recommended as it is capable of precisely discovering direct repeats that flank the acquired region (Hudson *et al.*, 2015). On the other hand, IslandPath-DIMOB and SIGI-HMM seem to have lower precision when predicting GI boundaries and tend to return fragmented horizontally transferred regions. Nevertheless, in the case of finding GIs via gene-based nucleotide bias approaches, both tools are favoured to generally anticipate more dispersed segments gained by HGT (Hsiao *et al.*, 2003, 2005; Waack *et al.*, 2006).

Identification of mobile elements

Mobile elements are DNA segments that can move within the genome or out to other organisms and while moving, it will bring along the donor genes to pass on to the recipient genome (Rankin *et al.*, 2011). Such an ability make these mobile elements a key

Table 1 List of tools applicable for the analysis of horizontal gene transfer events. Different computational tools for different platforms (web-based and operating systems) to analyze HGT genes

Category	Programs	Approach	URL	Platform	Reference
(a) Pan-genome analysis	EDGAR	A software framework for the comparative analysis of prokaryotic genomes.	http://edgar.computational.bio/	Web server	Blom <i>et al.</i> (2009)
	PGAT	A web-based database that compared multistrain microbial organisms' gene content and SNPs and impact of SNPs to encoded proteins.	http://nwrce.org/pgat	Web server	Brittnacher <i>et al.</i> (2011)
	PanGP	Integrates two sampling algorithms TR (totally random) and DG (distance guide) to perform pan-genome analysis in large scale bacterial genomes.	http://pangp.big.ac.cn/	Windows, Linux	Zhao <i>et al.</i> (2014)
	Panseq	Determine core and accessory region in genomes, SNPs within shared core regions and calculate loci in sets of accessory loci or core SNPs.	https://fz.corefacility.ca/panseq/	Web server, Windows, Linux	Xiao <i>et al.</i> (2015)
(b) Identification of atypical sequence signatures	geecee	A tool from the EMBOSS package to calculate fraction of GC per 100 bp within a gene or genome.	http://www.bioinformatics.nl/cgi-bin/emboss/geecee	Web server, Linux	Rice <i>et al.</i> (2000)
	GC-Profile	GC profile analysis by segmenting the genome.	http://tubic.tju.edu.cn/GC-Profile/		
	Web server Artemis	GC content (%) and its 2.5 SD cutoff from graph menu.	http://www.sanger.ac.uk/science/tools/artemis	Windows, Linux, Mac OS	Carver <i>et al.</i> (2008)
	IslandViewer	Integrate four GIs prediction tools: IslandPick, IslandPath-DIMOD, SIGI-HMM and Islander.	http://www.pathogenomics.sfu.ca/Webserver/islandviewer/	Web server	Bertelli <i>et al.</i> (2017)
(c) Identification of GIs	IslandPick ⁴	Identify GIs by using distance function, unique region only to query genome and conserved regions across genomes.	http://www.pathogenomics.sfu.ca/Webserver/islandviewer2/run_islandpick.php	Web server	Langille <i>et al.</i> (2008)
	IslandPath-DIMOB	Identify GIs by require dinucleotide bias and presence of mobility genes.	http://www.brinkman.mbb.sfu.ca/Linux/~mlangill/islandpath_dimob/	Linux	Hsiao <i>et al.</i> (2003, 2005), Langille <i>et al.</i> (2008)
	SIGI-HMM	It predicts GIs and putative donor of foreign genes based on codon usage analysis of gene or genome and HMM approach.	http://www.brinkman.mbb.sfu.ca/~mlangill/sigi-hmm/	Web server	Waack <i>et al.</i> (2006)
	Islander	A database that mapped GIs that were integrated into tDNAs, flanked by intact tDNAs and displaced tDNAs fragments, and contain integrase gene of tyrosine recombinase family.	http://bioinformatics.sandia.gov/islander/	Web server	Hudson <i>et al.</i> (2015)
(d) Identification of ME	Zisland explorer	Predict GIs based on segmental cumulative GC profile (from GC-profile tool).	http://cefg.uestc.edu.cn/Zisland_Explorer/	Web server, Windows, Linux, Mac OS	Wei <i>et al.</i> (2017)
	GIPro	Predict types of GIs: PAIs, MIs, RIs and Sis. It predicts by using genomic signatures deviation, tRNA genes, presence of MEs, and conserved regions.	https://www.bioinformatics.org/groups/?group_id=1180	Windows, Linux, Mac OS	Soares <i>et al.</i> (2015)
	ISQuest	Identify and annotate mobile genetic elements in raw read, partially assembled genome or fully assembled genome. It uses Blast to identify the MGEs.	https://sourceforge.net/projects/isquest/	Windows, Linux	Biswas <i>et al.</i> (2015)
	ISFinder PHASTER	A bacterial insertion sequences database. Identify and annotate phage sequences within bacterial genomes or plasmids by performing database comparison.	https://www-is.biotoul.fr/http://phaster.ca	Web server, Web server	Siguiet <i>et al.</i> (2006) Arndt <i>et al.</i> (2016)
(e) HGT detection	Alienness HGtector	Parse BLAST results against public libraries to identify candidate HGT in a genome of interest. Analyze BLAST hit distribution patterns based on sequence homology search hit distribution statistics.	http://alienness.sophia.inra.fr/https://github.com/DittmarLab/HGTector	Web server, Windows, Linux, Mac OS	Rancurel <i>et al.</i> (2017) Zhu <i>et al.</i> (2014)
	T-REX	All-against-all BLASTP search Reconstruct phylogenetic trees, reticulate networks and to infer the horizontal gene transfer events.	http://www.trex.uqam.ca/	Web server	Boc <i>et al.</i> (2012)

factor in evolution. Mobile elements include plasmid, bacteria-infecting viruses (bacteriophages), transposons, and insertion sequences. Examples of prediction tools for mobile elements are PHASTER for phages (Arndt *et al.*, 2016), ISFinder for identifying bacterial insertion sequences (Siguier *et al.*, 2006) and ISQuest for finding insertion sequences and transposons (Biswas *et al.*, 2015).

Identification of HGT Events Using Transcriptome Data

Since *de novo* whole genome assembly of a plant genome is complicated by the presence of repeat sequences, assessing HGT at the transcriptome level provides a direct approach to reveal the expression status of the genes. In host-parasite systems, a gene is considered horizontally acquired if it is phylogenetically placed nearer to its host rather than to its closest relatives. HGT detection using software is made possible for plants with the development of various tools, such as T-rex (Boc *et al.*, 2012), Alieness (Rancurel *et al.*, 2017) and HGTector (Zhu *et al.*, 2014). Nevertheless, some of these tools require specific files and preparation steps to conduct the HGT search. For instance, two newick trees generated for species and gene of interest are required as the input files. As with Alieness, a BLAST file of a whole proteome of interest is required to blast against any NCBI protein library. This tool calculates an Alien Index (AI) for early query protein and an AI > 0 indicates a possible HGT. HGTector takes one or more protein sets as input. In principle, this tool formulates a grouping scenario, calculates the three weights of each gene, defines certain cutoffs and then identifies the genes that exhibit atypical distribution.

In a case study that involves a parasitic plant (Section HGT in Plants), two web servers, OrthoVenn (see “Relevant Websites section”) (Wang *et al.*, 2015) and eggNOG-mapper of the EggNOG v 4.5 (see “Relevant Websites section”) (Huerta-Cepas *et al.*, 2016), were used to cluster orthologous genes across *Rafflesia* (parasite) and *Tetrastigma* (host) predicted proteomes. Homologous sequences were retrieved for each candidate HGT genes and were aligned using the multiple sequence alignment tool MUSCLE (Edgar, 2004) embedded in MEGA7 (Kumar *et al.*, 2016), which was later used to perform phylogenetic analysis through maximum likelihood searching.

Illustrative Case Studies

HGT in Bacteria

Here, we describe some cases of genes that were possibly transferred by HGT in a Gram-negative bacteria, *Burkholderia pseudomallei*, that in addition to being a versatile pathogen is notable for its highly plastic genome (Tumapa *et al.*, 2008). This flexibility is thought to be partly due to the HGT effect which turns this pathogenic soil bacteria into a highly adaptable organism that can live in a wide range of hosts (Currie, 2003) and has even been shown to actively respond and survive in very low nutrient environments (Mohd-Padil *et al.*, 2017). The pan-genome data of 48 complete *B. pseudomallei* genomes resulted in a total of 10,698 orthologous groups (OG) that encompassed 39% (4220 OGs) core genes and 61% (6478 OGs) accessory genes. Two observations of HGT are highlighted here; conserved hypothetical genes of *B. pseudomallei* and unique genes that were found in a specific *B. pseudomallei* strain.

Core hypothetical proteins in *B. pseudomallei*

In *B. pseudomallei* pan-genome data, 171 core genes encoding for hypothetical proteins (HPs) that were conserved in 48 complete *B. pseudomallei* genomes obtained from NCBI (Table 2). Further remote homology searching using BLAST (Altschul *et al.*, 1990) of these core HPs against a non redundant database revealed a range of conservation level in the sequences, from phylum down to species (Fig. 2).

Case 1: Hypothetical genes conserved in Burkholderiaceae family and two non-proteobacteria species

Up to December 2017, four hypothetical proteins – BPSL3171, BPSL3235, BPSS0337 and BPSS1590 (using the nomenclature for K96243) – are conserved in the Burkholderiaceae family and remote organisms from non proteobacteria phylum namely *Mumia flava* and *Streptomyces pluripotens*. Both bacteria were isolated from mangrove soil in Kuantan and Tanjung Lumpur of Pahang state, Malaysia, respectively (Lee *et al.*, 2014a,b). They are members of actinobacteria phylum that are highly adapted to various ecological environments and might be inhabitants of soil or aquatic environments, plant symbionts, plant pathogens or gastrointestinal commensal (Barka *et al.*, 2016). Mangrove soil is a highly dynamic ecosystem that is believed to force the soil bacterial populations to undergo rapid niche-specific adaptation. One mechanism for such adaptation is by acquiring beneficial genes from other bacteria in the same niche. Limited information is known about the *M. flava* genome as it is a novel actinobacterial strain (Lee *et al.*, 2014a), while *S. pluripotens* showed the presence of a wide-range of bacteriocins against pathogens such as *Staphylococcus aureus*, *Salmonella typhi* and *Aeromonas hydrophila* (Lee *et al.*, 2014b).

In terms of GC content, all four genes showed deviation from its chromosome GC average. Both BPSL3171 and BPSL3235 have lower GC content than K96243's large chromosome (67.7%), denoted by 51.46% and 55.84%, respectively. On another note, in the smaller second chromosome with GC percentage of 68.5%, the GC content in BPSS0337 is lower (62.59%), while it is higher in BPSS1590 (75.32%). This deviation is an informative indicator of horizontal gene transfer events that might have occurred at those positions.

Two domains of unknown function (DUFs), DUF1835 and DUF 3658, that have orthologs in both *M. flava* and *S. pluripotens* could also be found in the sequence encoding for BPSL3235. The latter domain can be found in bacteria and retains two highly conserved residues (Aspartic Acid and Arginine) that may play important functional roles. The gene is located in the same operon with that containing *bpsl3236*, a tetracycline (TetR) family transcriptional regulator that controls the level of susceptibility towards tetracycline antibiotics, a commonly used antibiotics against bacteria (Aleksandrov *et al.*, 2008; Grkovic *et al.*, 2002). There are also inverted repeats (palindrome) motifs found within 500 bp upstream and downstream of the *bpsl3235* gene together with additional motif of Rho-independent transcription terminator TERM 1195 located on the upstream region. According to Ooi *et al.* (2013), *bpsl3235* was found to be expressed in several conditions including during antibiotic treatment, osmotic stress, temperature stress, UV irradiation, oxidative stress and aerobic state.

Fig. 2 Number of cases for different conservation levels in *B. pseudomallei* core hypothetical proteins. Various distribution of conservation from phylum to species can be seen in core HPs of *B. pseudomallei*.

The other three hypothetical proteins, BPSL3171, BPSS0337 and BPSS1590 have similarities with *M. flava* only. Inverted repeats (palindrome) motifs are found at 500 bp downstream of each gene while the *bpsl3171* gene is located in the operon together with sequences encoding two other hypothetical proteins (BPSL3172 and BPSL3173). Both *bpsl3171* and *bpss1590* are flanked respectively by secretion system protein genes and type III secretion system gene together with type IV pilus protein. Whereas *bpss0337* is flanked by an insertion element gene and an *araC* family transcriptional regulator. Interestingly, *bpsl3171* is only expressed during anaerobic condition and *in vivo* infection (Ooi *et al.*, 2013) thus indicating that the gene may have important roles for *B. pseudomallei* survival and pathogenicity. In contrast, expression of BPSS0337 and BPSS1590 were detected in most conditions except *in vivo* infection conditions.

However, none of the genes discussed are predicted to be part of genomic islands. Since not all horizontally transferred genes must be located in a genomic island, this observation alludes to the possibility that these genes may have been transferred and have undergone amelioration, hence providing a possible explanation as to why some tools can no longer distinguish these regions as being foreign. In context, it can be assumed that these genes may have been horizontally transferred between *Burkholderia* and two non proteobacteria due to their presence in the same niche although the origin species of these genes remains unknown or have yet to be isolated and sequenced.

Unique genes in *B. pseudomallei*

In this discussion, a unique gene or singleton refers to a strain-specific gene that is found in the *B. pseudomallei* pan-genome (Tettelin *et al.*, 2005). In total, 13% (1352 OGs) of the accessory genes in *B. pseudomallei* are categorized as singletons. Such genes could also be of uncharacterized function, however due consideration should be given when annotating such singletons in a pan-genome dataset because homologs may actually exist in strains that do not yet have available genome sequences. It is recommended that these annotations are cross-checked against the vast non-redundant database in GenBank and also periodically revisited as the number of genomes in the pan-genome dataset increases.

Fig. 3 An ACT view showing an insertion of a region (8514 bp) in the first *B. pseudomallei* chromosome that absent in reference genome of K96243 strain. The highlighted region in yellow consists of D286.1_0401 and D286.1_0402 genes that may have arisen due to HGT events in the D286 strain. The region is not observed in the reference genome (upper section).

Case 1: Unique genes in *B. pseudomallei* that are also found in other soil bacteria

In *B. pseudomallei* strain D286 (Lee *et al.*, 2007), two adjacent unique genes encoding 393 residues (D286.1_0401) of a sequence with no other available homologs and 408 residues (D286.1_0402) of DNA-cytosine methyltransferase, are strain-specific. Extension of the genomic regions containing both genes suggests that a sequence with 8514 bp in the first chromosome of *B. pseudomallei* is observed in D286 strain while it is absent in reference genome of strain K96243 (Fig. 3). The low GC percentage of this region (53.01%), a relatively large deviation from the mean GC of its genome (67.87%) disturbs the genomic stability. The deviation gives an insight into gene acquisition of the strain although D286.1_0401 is predicted to be part of a genomic island albeit with low confidence and the extended discussed region has no predicted mobile elements.

The homology search using D286.1_0401 as a query yielded detectable similarities to five distant organisms from different phylums including proteobacteria (*Novosphingobium barchaimii* and *Pelobacter seleniigenes*) (Nasaringarao and Häggblom, 2007; Niharika *et al.*, 2013), acidobacteria (*Granulicella pectinivorans* and *Acidobacteria bacterium*) (Pankratov and Dedysh, 2010) and Terrabacteria group (*Brevibacterium* sp. 239c). Interestingly, all of them share the mutual characteristics of being physiologically diverse and capable of living in a wide range of environments, especially soil, although this is common of many bacteria. On the other hand, its adjacent gene of D286.1_0402, has a vast similarity to many other organisms including *G. pectinivorans*, *A. bacterium* and *Eubacterium plexicaudatum* (Pankratov and Dedysh, 2010; Wilkins *et al.*, 1974).

Case 2: Unique genes in *B. pseudomallei* detected as part of a genomic island

Based on available pan-genome data, four unique genes in the D286 strain were identified to reside within a 53,131 bp length GI region predicted by IslandViewer 4. The four genes are annotated as hypothetical gene (D286.1_3048), HNH endonuclease family protein, (D286.1_3063), ATPase (D286.1_3064) and hypothetical protein encoding gene, (D286.1_3071). The HNH endonuclease family protein, (D286.1_3063) and ATPase (D286.1_3064) share similarity with diverse remote genomes but no similarities to any from *Burkholderia* sp. while D286.1_3048 is similar but also appear to have orthologs in three *Burkholderia* sp.. The sequence encoded by D286.1_3071 shows similarity with only one hypothetical protein from *B. vietnamiensis*. Compared to the mean GC of its genome (67.87%), this region carries a lower GC percentage of 59.66%, indicating that foreign gene influx may have occurred at that position. This is supported by the finding of the presence of tRNA genes that is well known to be associated to GI that were obtained from foreign organisms (Tuller, 2011).

Around 20% of genes in the GI encode for hypothetical proteins. Our results show that this island also consists of a phage-related integrase gene next to the tRNA gene, proposing that this GI may possibly have been generated by a phage or plasmid with integrative functions (Odenbreit and Haas, 2002; Semsey *et al.*, 2002). In addition to the phage integrase family protein gene, another group of genes that were also present were those for components of the Type VI secretion system (T6SS) that is well known as a virulence factor for pathogenic bacteria and as a mechanism for protein transport across the cell envelope in proteobacteria

(Pukatzki *et al.*, 2006). Furthermore, there are also phage-related genes present, such as those encoding phage virion morphogenesis protein, phage tail protein and phage capsid protein. A part of the GI seems to be similar with other *B. pseudomallei* strains, however part of the region is missing in the reference genome of the K96243 strain. Thus, from the pan-genome data, we can obtain some indicators that these unique genes might be an effect of a HGT event.

HGT in Plants

Lateral gene transfer in parasitic flowering plants is known to occur via genomic DNA (Xi *et al.*, 2012), or via mRNA intermediates (Kim *et al.*, 2014). Therefore, HGT involving plants is studied using both genome (Yue *et al.*, 2012) and transcriptome (Kim *et al.*, 2014; Xi *et al.*, 2012; Zhang *et al.*, 2014, 2013) data whenever possible. Nuclear HGTs are less common among multicellular eukaryotes such as animals, fungi and plants (Richardson and Palmer, 2007) compared to organellar genes. However, a total of 47 horizontally acquired nuclear genes were identified from *R. cantleyi* using a combination of BLAST and phylogenomic approaches (Xi *et al.*, 2012). Using the same approach, an approximation of 24%–41% of the mitochondrial gene sequences were identified to be horizontally acquired from their host (Xi *et al.*, 2013).

Clustering of orthologous groups across two or more distant species results in a list of horizontally acquired candidate genes. Through reciprocal proteome clustering between *Rafflesia* and *Tetrastigma*, 59 orthologous clusters and 67 candidate orthologs were identified from OrthoVenn and eggNOG-mapper respectively to be *Tetrastigma*-related and these genes were subjected to phylogenetic analysis. Thirteen genes were identified to be transferred through HGT. Interestingly, only rhamnose synthase was similarly identified by the two approaches used in this case study and the analysis conducted by Xi *et al.* (2012). The remaining 12 genes were found to span across cell wall formation, degradation, defense mechanism, stress response, amino acid biosynthesis and glycolysis. Additionally, 24 *Rafflesia* genes were not grouped together, either with its closest relatives nor with *Tetrastigma*. Of these genes, six were reported to be horizontally transferred by Xi *et al.* (2012). The discrepancy could be attributed to the polyphyletic status or unresolved ambiguity exerted by the evolving elements.

Discussion and Future Directions

Several methods have been developed to improve the accuracy in addition to reducing the computational time to search for HGTs. Compared to the different approaches employed by Xi *et al.* (2012), the methods described here identifies much lower numbers of HGTs, possibly due to stringent parameters applied for orthologous clustering during the early search. This may rule out the set of genes that have lost the signatures of their donor as a result of evolution. In contrast, the classification of homologous sequences into the respective species presents a higher number of candidates for HGT identification in an organism of interest.

Choosing an appropriate method for HGT detection is not straightforward. It depends on the nature of the study, species of interest, computational resources and time. With the development of bioinformatic tools and pipelines, HGT detection can now be performed on large-scale data sets, covering both prokaryotes and eukaryotes. Care should be taken in order to avoid false positives that could lead to a pool of unresolved artifacts. For instance, despite the application of BLAST-based detection in some studies (Yoshida *et al.*, 2010; Zhang *et al.*, 2014, 2017), comprehensive follow up work is required to eliminate high false positives, such as misidentification of contaminant sequences, deficient taxon sampling, intriguing gene birth and death processes, improper rooting and frame-shift errors that must also be accounted for (Yang *et al.*, 2016). Similarly, incomplete lineage sorting during phylogeny construction can lead to inaccurate HGT identification (Than *et al.*, 2007).

To date, there is no true one-stop solution for the identification of genes that were potentially horizontally transferred. However, the results of tools used for sequence analysis and phylogenetics can be used and the relevant context provided to allow for inference of HGT events. As more genomes become available, it would perhaps be timely for a fit for purpose tool or pipeline to be developed for inferring HGT events despite such tools requiring significant capacity and resource allocations.

Gene Duplication and Speciation

Tiratha R Singh and Ankush Bansal, Jaypee University of Information Technology, Solan, India

© 2019 Elsevier Inc. All rights reserved.

Background

Significant progress has been made in the past few decades in understanding Darwin's theory of the origin of species. Different genomic methods have helped to understand the genetic variations and gene flow that makes new species (Magadum *et al.*, 2013; Shapiro *et al.*, 2016). Although new methods have not changed the previous speculations about how species formed, they have quickened the pace of information gathering (Reams and Roth, 2015). Compiling studies on hereditary investigations would be useful to answer queries of the upcoming generations on the relative occurrence and significance of various procedures that occur during speciation (Liu *et al.*, 2016).

Many 20th century biologists viewed genes as traits of species, exquisitely tuned to current utility. This resulted in the assumption that each species should possess different genes. Gene duplication was recognized, but was implicitly assumed to have occurred recently (Rose and Oakley, 2007). Many biologists now assume that most genes have their origins in gene duplication events, which happen throughout evolutionary history. As a result, many genes form families that have persisted for hundreds of millions of years.

Gene duplication events and results of such events play a crucial role in determination of the function of novel genes. There have been various models and theories that have emerged to support the concept of gene copies (Liu *et al.*, 2016; Singh *et al.*, 2009). However, a clear picture of gene duplication events is still not clear and needs more information to come to any conclusion. Different prediction software and tools based models such as hidden Markov models give insight to evolutionary functional properties and dynamics (Singh and Pardasani, 2009). Hence, understanding the gene duplication events and speciation is an essential step towards understanding and identifying the major mechanisms that are involved in the evolution (Seehausen *et al.*, 2014).

Gene Duplication

The evolutionary understanding of gene duplication events was first performed by Haldane and John (1932), who suggested that a redundant duplicate(s) of a gene may acquire divergent mutations and eventually emerge as a new gene. A gene duplication event was first noted by Bridges (1936) in the Bar locus in *Drosophila*. A substantial increase in the number of copies of a DNA segment can be brought by various types of gene duplication (White, 1977; Raj Singh, 2008). There are various studies where gene duplication and deletion events are being systematically observed (Ma *et al.*, 2014; Schacherer *et al.*, 2004; Simillion *et al.*, 2002; Stephens, 1951). Many types of duplications are recognized: First, partial gene duplication; second, complete gene duplication; third, partial chromosomal duplication; fourth, complete chromosomal duplication; fifth, genome duplication (Innan and Kondrashov, 2010; Conant and Wolfe, 2008; Panchy *et al.*, 2016). The first four are treated as regional duplicates as they do not alter the haploid set of chromosomes. The main reason for gene duplication includes uneven crossing over (Iñiguez and Hernández, 2017; Levasseur and Pontarotti, 2011; Qian and Zhang, 2014). Uneven crossing over in two nonaligned sequences gives a duplicated region on one chromosome along with deletion on second on the basis of the size of the nonaligned region. DNA sequence duplication in tandem results in a progressive increase in uneven crossing over, which ultimately increases the number of duplicate copies (Mendivil Ramos and Ferrier, 2012).

Partial Gene Duplication

Tandem duplication events in DNA sequences may provide information about genetic evolution events in terms of the complete gene while tandem duplication in a small region, or maybe in part of gene, ultimately results in mutations and is the cause of various diseases (Hu and Worton, 1992; Hu *et al.*, 1988). The duplication arrangement can be understood by taking the inference from molecular information lying in the sequence (Toll-Riera *et al.*, 2011). For instance, structure level changes induced by changes in nucleotide and amino acid sequence level influences the protein evolution. Toll-Riera *et al.* (2011) have demonstrated this by considering a large dataset of human and mouse orthologs protein and later mapping with PDB structures. Evidence from literature suggests that duplication may arise from either homologous (Alu-Alu) recombination or nonhomologous recombination, the latter possibly mediated by topoisomerases. For the dystrophin gene, in which most duplications have been identified, these recombination events are intrachromosomal, which suggests that unequal sister chromatid exchange is the major mechanism (Toll-Riera *et al.*, 2011).

Domain Duplication and Gene Elongation

A domain is a well-defined region within a protein that either performs a specific function within a protein, such as substrate binding, or constitutes a stable, independently folding, compact structural unit within the protein that can be distinguished from

all the other parts" (Li and Makova, 2001). Theoretically, several possible relationships may be envisioned between the structural domains and the arrangements of the exons in the gene, e.g., in many globular proteins, a more or less exact correspondence exists between exons of gene and the structural domains of the protein product. Alternate splicing is one of the main reasons for exon shuffling in a duplication event as there are always chances for repetition of a similar exon set again. In a considerable number of cases, several adjacent models were found to be encoded by the same exon (Li and Makova, 2001).

The vertebrate hemoglobin α and β chains, consist of four domains, whereas their genes consist of only three exons, the second of which encodes two adjacent domains. In *Caenorhabditis elegans*, a globin-encoding gene, during the evolution of a globin gene family from a four exon ancestral gene, several lineages lost some or all of their three introns, thereby, generating panoply of exon–intron permutations (Vogel *et al.*, 2005). In the majority of cases, a domain duplication at the protein level indicates that an exon duplication has occurred at the DNA level. Moreover, many proteins of present day organisms show internal repeats often correspond to functional or structural domains within the proteins. A survey of modern genes in eukaryotes shows that the internal duplications have occurred frequently in evolution. This gene duplication is one of the most important steps in the evolution of complex genes from the simple ones (Vogel *et al.*, 2005).

Theoretically, elongation of genes can also occur by other means; for example, a mutation change converting a stop codon into a sense codon can also elongate the gene, which could be a part of recoding event (Singh and Pardasani, 2009). Similarly, either insertion of a foreign DNA segment into an exon or the occurrence of a mutation obliterating a splicing site will achieve same result. These types of molecular changes most probably disrupt the function of the elongated gene. In the vast majority of cases, such molecular changes have been found to be associated with pathological manifestations. By contrast, duplication of a structural domain is less likely to be problematic. Indeed, such a duplication can sometimes even enhance the function of the protein produced for example by increasing the number of active sites (a quantitative change), thus enabling the gene to perform its function more rapidly and efficiently or by having a synergistic effect yielding a new function (a qualitative change) (Nacher *et al.*, 2010).

Emergence of novel function can be derived from partial gene as divergence in the sequence may lead to different functions. Complete gene duplication produces two identical paralogous copies (Nacher *et al.*, 2010). Duplicated genes can be divided into two types – Variant and invariant repeats. Invariant repeats are identical or nearly identical in sequence to one another. Variant repeats are copies of a gene that, although similar to each other, differ in their sequences to a lesser or greater extent. All the genes that belong to a certain group of repeated sequences in a genome are referred to as a gene or a multigene family. Functional and nonfunctional members of a gene family may reside in close proximity to one another on the same chromosome or they may be located on different chromosomes. A member of a gene family that is located alone at a different genomic location than the other members of the family is called an orphan. The term *superfamily* was coined by Dayhoff in order to distinguish closely related proteins from distantly related ones (Dayhoff and Schwartz, 1978). Proteins that exhibit at least 50% similarity to each other at the amino acid level are considered as members of a superfamily, for example, α and β globins are classified into two separate families and together with myoglobin they form the globin superfamily (Li and Makova, 2001). An important feature associated with gene duplication is that as long as two or more copies of a gene exist in proximity to each other, the process of gene duplication can be greatly accelerated in this region, and numerous copies may be produced. There may be two reasons for the general positive correlation between genome size and number of copies of RNA specifying genes. Either a large genome requires large quantities of RNA, or the number of RNA-specifying genes is simply a passive consequence of genome enlargement by duplication. Highly repetitive genes, like rRNA genes, are generally very similar to each other (Li and Makova, 2001).

One factor responsible for homogeneity may be purifying selection. In addition to invariant repeats, the genomes of higher organisms contain numerous multigene families whose members have diverged to various extents such as genes coding for isozymes, such as lactate dehydrogenase, aldolase, creatine kinase, carbonic anhydrase, and pyruvate kinase. Isozymes are enzymes that catalyze the same biochemical reaction but may differ from one another in tissue specificity, developmental regulation, electrophoretic mobility, or biochemical properties. Isozymes are encoded by different loci, usually duplicated genes, as opposed to allozymes, which are distinct forms of the same enzyme encoded by different alleles at a single locus (Li and Makova, 2001; Vogel *et al.*, 2005).

Exon Shuffling

There are three types of exon shuffling: (1) Exon duplication, (2) exon insertion, and (3) exon deletion. Exon duplication refers to the duplication of one or more exons in a gene and so is a type of internal duplication (Pathy, 1999). Exon insertion is the process by which structural or functional domains are exchanged between proteins or inserted into a protein. Exon deletion results in the removal of a segment of amino acids from the protein. All types of shuffling have occurred in the evolutionary process of creating new genes (Kolkman and Stemmer, 2001; Pathy, 1999). Exon shuffling could be represented through various phases as shown in Fig. 1.

Mosaic or Chimeric Proteins

A mosaic or chimeric protein is a protein encoded by a gene that contains regions that are also found in other genes (Nicolson, 2015; Singer and Nicolson, 1972). The existence of such proteins indicates that exon shuffling has occurred during the evolutionary history of their genes. The first described mosaic protein was tissue plasminogen activator (Iñiguez and Hernández, 2017). For an exon to be inserted, deleted, or duplicated without causing a frameshift in the reading frame, certain phase limitations of the exonic structure of the gene must be respected. Mosaic proteins can be made when two adjacent genes are transcribed together and are therefore made into the same protein.

Fig. 1 Schematic representation of exon shuffling. Numbers above the box represent the position of nucleotide.

To understand this, we need to consider introns in terms of their possible positions relative to the coding regions (Nicolson, 2014). Introns residing between coding regions are classified into three types according to the way in which the coding region is interrupted (Jeon, 2004). An intron is of phase 0 if it lies between two codons, of phase 1 if it lies between the first and second nucleotide of a codon, and of phase 2 if it lies between the second and third nucleotides of a codon. Exons are grouped into classes according to the phases of their flanking introns. Here are four middle exons, said to be (0–0), (0–1), (0–2), and (1–2) exons. An exon that is flanked by introns of the same phase at both ends is called a symmetrical exon, otherwise it is asymmetrical. The first exon (middle) is a symmetrical exon, represented by black box. The length of a symmetrical exon is always a multiple of three nucleotides. Only symmetrical exons can be duplicated in tandem or deleted without affecting the reading frame.

Duplication or deletion of asymmetrical exons would disrupt the reading frame downstream. Similarly, only symmetrical exons can be inserted into introns, but with the restriction of, a 0–0 exon can only be inserted in phase-0-introns, a 1–1 exon is inserted into phase 1 introns, and 2–2 exons into phase-2 introns for avoiding frameshifts. All the exons coding for the modules of mosaic proteins are symmetrical. Since nonrandom intron phase usage is a necessary consequence of exon duplication or insertion, this property may be used as a diagnostic feature of gene assembly through exon shuffling. In terms of splicing, introns are classified into two categories, self-splicing and spliceosomal (Wang *et al.*, 2013). The vast majority of introns in eukaryotic nuclear genes are spliceosomal. Self-splicing introns play a vital role in their own removal, some regions of the introns are involved in self-complementary interactions important for forming the 3-D structure possessing splicing activity. Exon shuffling probably did not play a role in the formation of genes in the early stages of evolution. Exon shuffling came to full bloom with the evolution of spliceosomal introns, which do not play a role in their self excision. These introns contain mainly nonessential parts and therefore could accommodate quantities of “foreign” DNA (Wang *et al.*, 2013).

Exonization and Pseudoexonization

Exonization is the process through which an intronic sequence becomes an exon. An exon created by exonization must abide by the same rules of exon insertion (Schmitz and Brosius, 2011). The opposite process is called pseudoexonization. It occurs when nonfunctionalization affects a single exon rather than the entire gene. The result is the creation of a pseudoexon, and the most obvious consequence of such a process is gene abridgement (as opposed to gene elongation). Pseudoexons are often created by the nonfunctionalization of internal gene duplications, for example, the aggrecan gene in rat contains 18 repeated exons and one pseudoexon. Some complex biological functions that require several enzymes may be specified by genes encoding different combinations of protein modules. In some species we may find single-module proteins, while in others we may find different combinations of multimodular proteins, for example, genes in a multistep process in the synthesis of fatty acids from Acetyl Co-A require seven enzymatic activities and an acyl-carrier protein. In fungi, these activities are distributed between two nonidentical polypeptides encoded by two unlinked intronless genes, FAS1 and FAS2. FAS1 encodes two and FAS2 encodes five enzymatic activities. In most bacteria, however, these functions are carried on by discrete monofunctional proteins (Schweizer and Hofmann, 2004).

In animals, key functions associated with fatty acid metabolism are controlled with a single polypeptide chain called fatty acid synthase. The fatty acid synthase gene in fungi and mammals are most probably mosaic proteins that have assembled from single-domain proteins like the ones found in bacteria (Stower, 2013). The fact that arrangement of domains is different in fungi from that in mammals indicates not only that the two lineages evolved multimodularity independently, but also that different strategies may be employed in the assembly of genes encoding multimodular proteins.

Nested and Overlapping Genes and Their Association With Speciation

In addition to gene duplication and exon shuffling, many other mechanisms for producing new genes or polypeptides are available. Few such entities are overlapping genes, pseudogenes, and nested genes.

Overlapping Genes

A DNA fragment (segment) can code for more than one gene product by using different reading frames or different initiation codons. This phenomenon of overlapping genes is widespread in DNA and RNA viruses, as well as in organelles, and bacteria, also known in nuclear eukaryotic genomes (Makalowska *et al.*, 2005). Overlapping genes can also arise by the use of the complementary strand of a gene; for example, genes specifying tRNA^{ILE} and tRNA^{GLN} in the human mitochondrial genome are located on different strands and there is a three-nucleotide overlap between these that reads 5'-CTA-3' in the former and 5'-TAG-3' in the latter (Makalowska *et al.*, 2005). The rate of evolution is expected to be slower in stretches of DNA encoding overlapping genes than in similar DNA sequences that only use one reading frame. The reason is that the proportion of nondegenerate sites is higher in overlapping genes than in nonoverlapping genes, thus vastly reducing the proportion of synonymous mutations out of total number of mutations (Johnson and Chisholm, 2004; Normark *et al.*, 1983). Since gene duplication is a widespread phenomenon for the maintenance of overlapping genes, it would require quite strong selective pressure (against increasing genome size). Studies on aminoacyl tRNA synthetases indicate that overlapping genes may have played a momentous role in the evolution of life (Johnson and Chisholm, 2004; Normark *et al.*, 1983).

Alternate Splicing

Alternative splicing of a primary RNA transcript results in the production of different mRNAs from the same DNA segment, which in turn may be translated into different polypeptides (Baralle and Giudice, 2017). There are two types of exons: Constitutive, that is, exons that are included within all the mRNAs transcribed from a gene, and facultative, that is, exons that are sometimes spliced in and sometimes spliced out (Kornblihtt *et al.*, 2013). There are different types of alternative splicing; the most trivial form is the intron retention (Lee and Rio, 2015). However, more commonly, intron retention results in the premature termination of translation due to frameshifts. Sometimes, alternative splicing involves the use of alternative internal donor or acceptor sites, that is, excisions of introns of different lengths with complementary variation in the size of neighboring exons. Such use of competing splice sites was found in several transcription units of adenoviruses, as well as in eukaryotic cells such as the transformer gene in *Drosophila melanogaster* (Lee and Rio, 2015). Some cases of alternative splicing involved the use of mutually exclusive exons, that is, two exons are never spliced out together, nor are both retained in the same mRNA for example, M1 and M2 from a single gene by mutually exclusive use of exons 9 and 10. A special case of mutual exclusivity is the cassette exon (Roy *et al.*, 2013). A cassette is either spliced in or spliced out in the alternative mRNA molecules. Alternative splicing has often been used as a means of developmental regulation (Wang *et al.*, 2015). A very intriguing situation is seen in several genes involved in the process of sex determination in *D. melanogaster*. At least three genes, doublesex (*dsx*), Sexlethal (*sxl*), and transformer (*tra*), are spliced differently in males and females (Wang *et al.*, 2015). There is rich literature available on alternate splicing and its distribution in almost all available lineages.

Intron-Encoded Proteins and Nested Genes

An intron may sometimes contain an ORF that encodes a protein or part of a protein that is completely different in function from the one encoded by the flanking exons (Kumar, 2009). In many cases, intron-encoded protein genes are located within type-I self-splicing introns. From a mechanistic point of view, an intron-encoded protein gene that is transcribed from the same strand as the neighboring exons may be regarded as special instance of alternative splicing (Lee and Chang, 2013; Yu *et al.*, 2005). When an intron-encoded protein gene is transcribed from the opposite strand of the other gene, it is referred to as a nested gene. A case of nested genes was found in *Drosophila*, where a pupal cuticle protein gene is encoded on the positive strand of an intron within the gene encoding the purine pathway enzyme glycineamide ribotide-transformylase (Kaer *et al.*, 2011).

Functional Convergence

Function of a protein is frequently determined by only a few of its amino acids; a protein performing one function may sometimes arise from a gene encoding a protein performing a markedly different function. If the new function is performed in other species by proteins of unrelated structure and descent, functional convergence may occur. The myoglobin of abalone *Sulculus* consists of 377 amino acids, which are 2.5 times larger than myoglobins belonging to the globin superfamily (Suzuki *et al.*, 1996). Functional convergence provides a robust parameter associated with the existence of a functional protein for a family or superfamily. This convergence is reflected in various levels of organisms at the family and superfamily level based upon rate of selection pressure.

RNA Editing

RNA editing is a molecular process by which protein-coding gene change its message. One of the most common types of RNA editing is C-to-U conversion. This conversion may occur partially or completely in some tissues but not in others, leading to differential gene expression. Occasionally, it can produce a new protein with a different function from the unedited transcript, for example, apolipoprotein B gene, one of the lipid carriers in the blood (Cooper, 1999). There are two types – Apo B-100 and apo B-48. Despite differences in length, amino acid sequences of the gigantic protein apo B-100 (4536 amino acid) with that of

apo B-48 (2152 amino acid), the result of alignment for the alignable part is 100% identity. It was found that apo B-48 is translated from a very long mRNA that is identical to that of apo B-100 with the execution of an in-frame stop codon resulting from the RNA editing of codon 2153 from CAA (Gln) to UAA (stop). Thus, by using RNA editing, two quite different proteins are produced from the same gene (Cooper, 1999). (Figs. 2,3,4,5).

Gene Sharing

Gene sharing means that a gene acquires and maintains a second function without divergent duplication and without loss of the primary function. Gene sharing may, however, require a change in the regulation system of tissue specificity or developmental timing (Cvekl and Zheng, 2009; Patthy, 2007). In literature, the term “multifunctional protein” is frequently used instead of “gene sharing.” Gene sharing was first discovered in crystallins, which are the major water-soluble proteins in the

Fig. 2 Mechanism of RNA editing may leads to truncation.

Fig. 4 Duplication and Speciation Events.

Fig. 5 Evolutionary relationship among retro elements.

eye lens, and whose function is to maintain lens transparency and proper light refraction (Cvekl and Zheng, 2009). Gene sharing might be a fairly common phenomenon, also suspected for several proteins in the cornea and other tissues. Gene sharing clearly adds to the compactness of the genome, even though compactness does not seem to have a high priority in eukaryotes (McKay, 2008).

Molecular Repair

The more we learn about the evolution of genes, the more we recognize that true innovations are only rarely produced during evolution. Many proteins that were originally considered to be relatively recent evolutionary additions turned out to be derived from ancient proteins (McKay, 2008). Besides, all the discussed mechanisms that facilitate tinkering at the molecular level are gene conversion and transposition. We may deduce that molecular tinkering is most probably the paradigm of molecular evolution, and it is reasonable to assume that tinkering also characterizes the evolution of morphological, anatomical, and physiological traits as well.

Gene Gain and Loss and Speciation Events

Gene Loss

More than 7000 diseases and disorders were documented in research papers and literature sources, which state that mutations have a crucial role in destroying and gaining function at the gene level (McKusick, 2007). A number of such mutations either get deleted at a very fast rate from population or sustained at very low frequency due to genetic drift. If there are many copies of genes present and functions normally then deleterious mutations which occur more often collate together compared to significant ones. Repeated duplicate genes usually become nonfunctional instead of being a new gene (Stone *et al.*, 1998).

Lateral Gene Transfer

Lateral gene transfer (LGT) is a process that makes complicated distribution of genes and dissimilar phylogenies with an rRNA tree. Still there is a debate on robust organismal phylogeny over extensive LGT (Kettler *et al.*, 2007). In case there is a presence of a core set of genes that are resistant to LGT, then there should be a reflection of vertical descent and ascent along with cell division. Moreover, various next generation sequencing techniques like metagenomics, genomics, and proteomics pave a path in understanding the core mechanism of LGT. In particular, it will be informative to know the complete genome diversity (Kettler *et al.*, 2007).

Dating Gene Duplication and other Computations

Dating Gene Duplications

Two genes are said to be paralogous if they are derived from a duplication event, but orthologous if they are derived from a speciation event.

Here, genes a and b were derived from the duplication of an ancestral gene and are paralogous, while gene a from species 1 and gene a from species 2 are orthologous, as are genes b from species 1 and gene b from species 2 (Chen *et al.*, 2000). We can estimate the date of duplication, T_D , from sequence data if we know the rate of substitution in genes a and b. The rate of substitution can be estimated from the number of substitutions between the orthologous genes in conjunction with knowledge of the time of divergences T_S between species 1 and 2. For gene a, let K_a be the number of substitutions per site between the two species. Then the rate of substitution in gene a, γ_a is estimated by:

$$\gamma_a = \frac{K_a}{2T_S} \quad (1)$$

The rate of substitution in gene b, γ_b can also be obtained in a similar way. The average substitution rate for the two genes:

$$\gamma = \frac{\gamma_a + \gamma_b}{2} \quad (2)$$

To estimate T_D , we need to know the number of substitutions per site between gene a and b (K_{ab}). This number can be estimated from four pairwise comparisons: (1) Gene a from species 1 and gene b from species 2, (2) (Robinson-Rechavi *et al.*, 2004). Gene a from species 2 and gene b from species 1. (3) Gene a and gene b from species 1. (4) Gene a and b from species 2. From these four estimates, we can compute the average value for K_{ab} from which we can estimate T_D as:

$$TD = \frac{K_{ab}}{2\gamma} \quad (3)$$

In case of protein coding genes, by using the number of synonymous and nonsynonymous substitutions separately, we can obtain two independently estimates of T_D . The average of these two may be used as the final estimate of T_D . Sometimes problems are due to concerted T_D estimation. Another method for dating gene duplication events is to consider the phylogenetic distribution of genes in conjunction with paleontological data pertinent to the divergence date of the species in question (Zhou *et al.*, 2010).

Unprocessed Pseudogenes

The silencing of a gene due to deletion in a nucleotide and causing deleterious mutation ultimately results in production of pseudogene. Such pseudogenes do not undergo RNA processing. Unprocessed pseudogenes may be the result of derivation from nonfunctionality of a duplicate functional gene. There is much less chance that functional genes come into existence without duplication. Unprocessed pseudogenes may result in various diseases and disorders like frameshift mutation, nonmature stop codon, and misorientation of sliced transcripts or regulatory elements; therefore, it is easy to identify a change in sequence in terms of mutations resulting directly in gene silencing (Tutar, 2012). It is possible in some cases to identify the mutation responsible for nonfunctionalization of a gene through a phylogenetic analysis, for example, human pseudogene $\psi\eta$ in the b-globin family contains numerous defects, each of which could have been sufficient to silence it (Pink *et al.*, 2011). The b-globin clusters in chimpanzee and gorilla were found to contain the same number of genes and pseudogenes as in humans, indicating that the pseudogenes were created and silenced before these three species diverged from one another.

Interestingly, mutations that cause nonfunctionalization are only rarely missense mutations, most probably because such mutations result in the production of defective proteins that may be incorporated into final biological products and thus may have deleterious effects. Because unprocessed pseudogenes are usually created by duplication, they usually found in the neighborhood of the homologous functional genes from which they have been derived.

Unitary Pseudogenes

The pseudogene has no functional correlation with the human genome, called unitary pseudogene. Guinea pigs and humans suffer from scurvy unless they consume L-ascorbic acid in their diet, because they lack a protein called L-gulonono-y-lactone oxidase, an enzyme that catalyzes the terminal step in L-ascorbic acid synthesis (Pink *et al.*, 2011). In humans, L-gulonono-y-lactone oxidase is a pseudogene that contains molecular defects as the deletion of at least two exons (out of 12), deletions and insertion of nucleotides in the reading frame, and obliterations of intron-exon boundaries (Pink *et al.*, 2011). It has been assumed that the guinea pig and human ancestors managed to survive on a naturally ascorbic acid-rich diet; hence, the loss of this enzyme did not reflect a disadvantage.

Case Studies

There are several case studies where bioinformatics has been implemented successfully to connect molecular evolution events with their functional consequences. Genomics studies paved the path to understand variation at the genomic level through phylogenetic approaches (Pradhan *et al.*, 2017; Wang *et al.*, 2018). Further network reconstruction approaches using co-expression network modules also helps to trace the gene duplication events (Feng *et al.*, 2016; Malviya *et al.*, 2016). For instance, phylogenetic investigation of human FGFR-bearing paralogs favors piecemeal duplication theory of vertebrate genome evolution (Ajmal *et al.*, 2014). All given studies indicate that duplication and speciation events are very much diverse in nature and take many years to evolve and confirm to contribute to significant changes.

Tools and Methods

S.No.	Tool or method	Description	References
1.	Control-FREEC CNV detection: HTS analysis	A tool for detection of copy-number changes and allelic imbalances (including LOH) using deep-sequencing data. Control-FREEC automatically computes, normalizes, segments copy number and beta allele frequency profiles, then calls copy number alterations and LOH. The control (matched normal) sample is optional. The program can also use mappability data (files created by GEM).	Boeva <i>et al.</i> (2012, 2011)
2.	mrCaNaVaR micro-read Copy number variant regions	A copy number caller that analyzes the whole-genome next-generation sequence mapping read depth to discover large segmental duplications and deletions. mrCaNaVaR also has the capability of predicting absolute copy numbers of genomic intervals.	Alkan <i>et al.</i> (2009)
3.	forestSV Structural variant detection: HTS analysis	Integrates prior knowledge about the characteristics of SVs. forestSV is a statistical learning approach, based on Random Forests, that leads to improved discovery in high throughput sequencing (HTS) data. This application offers high sensitivity and specificity coupled with the flexibility of a data-driven approach. It is particularly well suited to the detection of rare variants because it is not reliant on finding variant support in multiple individuals.	Michaelson and Sebat (2012)
4.	CTDGFinder Duplication detection: HTS analysis	Formalizes and automates the identification of clusters of tandemly duplicated genes (CTDGs) by examining the physical distribution of individual members of families of duplicated genes across chromosomes. Application of CTDGFinder accurately identified CTDGs for many well-known gene clusters (e.g., Hox and beta-globin gene clusters) in the human, mouse, and 20 other mammalian genomes. Examination of human genes showing tissue-specific enhancement of their expression by CTDGFinder identified members of several well-known gene clusters (e.g., cytochrome P450s and olfactory receptors) and revealed that they were unequally distributed across tissues. By formalizing and automating CTDG identification, CTDGFinder will facilitate understanding of CTDG evolutionary dynamics, their functional implications, and how they are associated with phenotypic diversity.	Ortiz and Rokas (2017)
5.	cn.MOPS Copy number estimation by a Mixture Of PoissonS	A data processing pipeline for copy number variations and aberrations (CNVs and CNAs) from next generation sequencing (NGS) data. The package supplies functions to convert BAM files into read count matrices or genomic ranges objects, which are the input objects for cn.MOPS. It models the depths of coverage across samples at each genomic position. Therefore, it does not suffer from read count biases along chromosomes. Using a Bayesian approach, cn.MOPS decomposes read variations across samples into integer copy numbers and noise by its mixture components and Poisson distributions, respectively.	Klambauer <i>et al.</i> (2012)
6.	RDXplorer CNV detection: HTS analysis	A computational tool for copy number variants (CNV) detection in whole human genome sequence data using read depth (RD) coverage. CNV detection is based on the event-wise testing (EWT) algorithm. The read depth coverage is estimated in nonoverlapping intervals (100 bp Windows) across an individual genome based on the pileup generated by SAMTools.	Yoon <i>et al.</i> (2009)
7.	cnvHiTSeq CNV detection: HTS analysis	A set of Java-based command-line tools for detecting copy number variants (CNVs) using next-generation sequencing data.	Bellos <i>et al.</i> (2012)

Conclusion

Gene duplication and speciation are two prominent mechanisms for finding clues for evolution. Phylogenetic analysis helps researchers to understand the ancestral association of species or sequence of their interest. Gene duplication events, exon shuffling,

and speciation have a potent role in the process of evolution and to study convergence and divergence from ancestral data. This article provides descriptive information about basic concepts of phylogeny that may help students and researchers to become aware of terminologies used in gene duplication and speciation analysis. It is presented in a way where basic to advanced level information is being compiled on the diverse topics and it is estimated that this information will serve as comprehensive information to students, faculty members, and researchers working in this area. It reflects how bioinformatics can shape a computational pipeline for the analysis of biological data in an evolutionary scenario and will help the evolutionary biologists also to implement bioinformatics at some level for further exploration of basic principles.

Epidemiology: A Review

Vijayaraghava S Sundararajan, Ministry of Environmental Agency, Singapore; Bioclues.org, Hyderabad, India and Bioclues.org, Hyderabad, India

© 2019 Elsevier Inc. All rights reserved.

Introduction

Those living in the tropics and subtropical regions are at higher risk of dengue fever and dengue hemorrhagic fever and epidemics occur unexpectedly and can cause a great concern to the healthcare authorities. Climate, demography and ecology, urbanization are vital reasons in dengue transmission and epidemiology.

Dengue virus, an arbovirus that is transmitted by *Aedes* mosquitos in the tropics and subtropics of the world, causes an estimated 390 million infections per year, resulting in 96 million clinically symptomatic cases (Bhatt *et al.*, 2013a). DENV has four serotypes (DENV-1, DENV-2, DENV-3, and DENV-4) that each circulate worldwide. Spatial propagation of long-distance spread over large geographical distances is difficult to measure directly, but epidemiological coupling of locations revealed by synchrony in population-level disease patterns has been used successfully to infer mechanisms of spread (Grenfell *et al.*, 2001; Viboud *et al.*, 2006; Rohani *et al.*, 1999).

Dengue virus is transmitted mainly by *Aedes aegypti* and *Aedes albopictus* mosquitoes (Rosen *et al.*, 1983). World Health Organization has estimated that there are 50–100 million dengue infections per year (Rigau-Pérez *et al.*, 1998) and a recent study estimates that this figure to 390 million, of which ~96 million are symptomatic (Bhatt *et al.*, 2013b). Dengue infection in humans is mostly self-limiting although antiviral drugs are under development (Lim *et al.*, 2013; Rathore *et al.*, 2011). Some dengue cases may require hospital admission, and the more severe manifestations of dengue may lead to death (Murphy and Whitehead, 2011) and case fatality rates of dengue fever and severe dengue vary from 0%–5% to 3%–5% (Halstead, 1999).

DENV is a positive sense single stranded RNA virus of the genus *Flavivirus*, genome of approximately 11.8 kb encodes for a single polypeptide arranged in three structural (Capsid-pre-Membrane-Envelope) and seven non-structural (NS) proteins (NS1-NS2A-NS2B-NS3-NS4A-NS4B-NS5). The exposure to a particular serotype of DENV elicits type-specific life-long immunity (Simmons *et al.*, 2012) and display high mutation rates as a result of the error-prone RNA polymerase activity during genome replication (Steinhauer *et al.*, 1992). Genetic recombination further facilitates their opportunity for genetic novelty (Behura and Severson, 2013) and results in genetically diverse virus populations consisting of multiple genotypes of monophyletic nature. RNA virus populations often appear to exist as ensembles of mutant spectra that collectively behave as “quasi-species” (Domingo *et al.*, 2012) and serotype is composed of highly heterogeneous genotypes that demonstrates geographical-wide pattern spread (Holmes and Twiddy, 2003).

Dengue fever replaced malaria as the most important mosquito-borne disease in Singapore in the mid-1960s and attention is on vector source reduction through surveillance, enforcement, community engagement, careful urban planning and operational research. *Aedes* house index was successfully reduced to 50% in 1960s and further to a less than 5% by the late 1970s and dengue incidence reduced (Chan *et al.*, 1977; Goh, 1997, 1995; Chan *et al.*, 1971). However, dengue fever started to resurge in the country in 1980s, in a typical 5–6 year epidemic cycle and epidemics escalated within each cycle during the last decade even though house index was below 1% (Koh *et al.*, 2008; Lee *et al.*, 2010; Ler *et al.*, 2011). The geo-expansion of *A. aegypti* and resurgence is due to an increase in human population density, low herd immunity resulting from long periods of low transmission, local transportation that facilitates virus dissemination, virus importations and the (Ang *et al.*, 2015; Yew *et al.*, 2009; Goh and Yamazaki, 1987; Low *et al.*, 2015).

Research Studies

The entomological surveillance show caused an increase in both larval and adult *Aedes aegypti* (main source of vector transmission) population during the epidemic season. The ground conditions are conducive to sustain virus transmission on a longer period causing uncontrollable epidemic of dengue.

Region-Wide Synchrony and Traveling Waves of Dengue Across Eight Countries in Southeast Asia (Panhuis *et al.*, 2015)

The spatial and temporal dynamics of dengue transmission are poorly understood, limiting disease control efforts. A study with a large-scale dataset and analysed continental-scale patterns of dengue in Southeast Asia, travel pattern of dengue was studied and reported.

Dengue Transmission: Strong synchrony over the region for dengue cycles is reported. Statistically significant multiannual cycles changed over time, the highest in 1993–2004. In comparison, the average power of annual cycles was more constant over time but reduced in 1997–2001. The regional median for annual cycles was consistent over time, ranging between 0.50 and 0.64. The average synchrony decreased as the distance between province pairs increased up to ~1000 km. Synchrony of multiannual cycles peaked at 0.55 [95% confidence interval (95% CI)=0.45–0.67] compared with annual cycles.

Climate: The dengue cycles in 1997–2001 coincided with high temperatures across most latitude; but not with an anomaly in precipitation. High temperatures in these years were related to the strongest El Niño episode of the past century (Slingo and Annamalai, 2000; Webster and Palmer, 1997). We measured a strong wavelet coherency (>0.8) between multiannual dengue cycles and the Oceanic Niño Index (ONI) during 1993–2002 and during 2009–2010 for almost all provinces.

Travel Waves: Epidemic timings between provinces were measured and found, positive θ indicated that a province was timed earlier (leading ahead) vs. the other, and a negative θ indicated that a province was timed later (lagging behind). Provinces with outgoing traveling waves were located in west Thailand and the Bangkok area, central Laos (Savannakhét and Khammouan), and southern Philippines (Bohol).

Data and methods: Monthly dengue surveillance data and corresponding population (U.S. Census Bureau, 2014) and climate data (Fan and van den Dool, 2008; Becker *et al.*, 2013; Center for International Earth Science Information Network CIESIN, Columbia University, Centro Internacional de Agricultura Tropical (CIAT), 2005) at the provincial level (GADM, 2013) were available for 273 provinces in Thailand, Cambodia, Laos, Vietnam, Malaysia, Singapore, the Philippines, and Taiwan. Province names were standardized based on the administrative levels. Wavelet analysis which is well suited to characterize epidemiological time series is used isolate cycles with multiannual and annual periodicities. Synchrony between provinces was derived as the pairwise Pearson correlation coefficient with timing and amplitude of signals. Wavelet Coherency uses wave transforms of two time series to indicate their localized phase relationship in a time–frequency spectrum. Phase angles for annual and multiannual cycles as indicators of epidemic timing were computed. Traveling waves for a province is computed as a statistically significant positive linear association between θ and geographical distances between that province and the other provinces. Sensitivity analysis is conducted on the effect of the value for the wavelet parameters ω_0 and δj on synchrony.

The multi-country collaborative study improved insight that may lead to improved prediction of dengue transmission patterns and more effective disease surveillance and control efforts.

Three-Month Real-Time Dengue Forecast Models: An Early Warning System for Outbreak Alerts and Policy Decision Support in Singapore (Shi *et al.*, 2016)

Statistical models are built through machine learning methods in deriving potential recurrent infectious dengue outbreaks. In this study models are built with data that are available at the time of forecast, to forecast weeks or months, to get predictive performance, and be able to process new data rapidly. Weekly covariates were used to match the frequency of reported dengue data (Ministry of Health), time horizon used for all variables was January 2001 to December 2012.

Case data is downloaded as the weekly number of cases (natural log–transformed, + 1) from Ministry of Health, Singapore. *Population data* (mid-year) is retrieved from Singapore Department of Statistics for residents and foreign non-residents (natural log–transformed). Weekly mean temperature (T) in degrees Celsius, maximum hourly temperature, number of hours of high temperature ($>27.8^\circ\text{C}$) each week, and weekly relative humidity (RH) were obtained from Meteorological Services, Singapore. *Vector surveillance* weekly breeding percentage (BP) is an in-house index developed by NEA that provides an estimate of the proportion of *Ae. aegypti*, the primary vector of dengue in Singapore is calculated for the study. *Trend and seasonality data* with climatic factors (dengue is affected by other factors such as changes to vector control and circulating serotypes) and non-climatic factors (disease dynamics, dengue incidence into terms for trend and for annual seasonality) are derived.

The Least Absolute Shrinkage and Selection Operator (LASSO) is a technique that has inspired much interest in the statistical methodology community on “small n large p ” problems (Tibshirani, 1996). This framework use logistic regression selecting parameters to be included in the model rather than optimizing the (log) likelihood $L(y|\beta, x)$ for dependent variable y , independent variables x and coefficients β , as in standard regression. Covariates were considered at lags of up to 20 weeks based on the findings (Hii *et al.*, 2012a,b), but in contrast to their approach, we allowed the effect of a single factor (such as temperature) to have multiple lags in influencing future dengue cases.

Result: 12-week forecasts including 95% prediction intervals for various time points over the period 2001–2002 are reported. Also the forecasts at various time points in Singapore’s record-breaking 2013 epidemic, in which 22,170 cases were reported, are presented.

Epidemiology studies are challenging as local weather conditions within a region differs significantly. Integrating weather data into predictive models may not be always feasible as long term data not available.

Intra-Epidemic Evolutionary Dynamics of a Dengue Virus Type 1 Population Reveal Mutant Spectra That Correlate With Disease Transmission (Hapuarachchi *et al.*, 2016a)

Environmental Health Institute (EHI) received blood samples obtained from dengue suspected patients through an island wide network of hospitals and general practitioners during November 2012 to May 2014 for the DENV infection confirmed by SD Bioline Dengue Duo kit. All NS1 positive samples were subjected to serotyping. All consented DENV positive samples were used for genome sequencing as part of the existing virus surveillance programme.

Data: Virus strains were isolated from acute-phase sera (Koo *et al.*, 2013) and a maximum of three passages was done for each sample based on the original virus load. Viral RNA was extracted from sera using the QIAGEN viral RNA mini kit. The complementary DNA (cDNA) was synthesized using extracted RNA (Koo *et al.*, 2013). DENV serotypes were determined by using a

real-time PCR assay (Koo *et al.*, 2013; Lai *et al.*, 2007). Whole genome and envelope (E) gene sequences were generated directly from patient sera, whereas whole genome sequencing was performed on strains isolated from respective patient sera. Raw nucleotide sequences were assembled using the Laser gene package. Contiguous sequences were aligned in Bio-Edit (Hall, 1999).

Methods: The whole-polyprotein based maximum clade credibility tree was constructed using the Bayesian Markov Chain Monte Carlo (MCMC) method implemented in the BEAST (Drummond *et al.*, 2012). Based on jModeltest (Darriba *et al.*, 2012), the general time reversible model with gamma distribution and invariant sites (GTR+G+I) were used together with an uncorrelated log-normal relaxed molecular clock model. The dataset included 38 whole polyprotein sequences generated in this study and 44 DENV-1 sequences retrieved from GenBank database. Of 83 whole genomes generated, only 38 sequences representative of each variant were included in the phylogenetic analyses to minimize overcrowding.

Protein Data Bank (PDB) structures 3J2P (Zhang *et al.*, 2013) which illustrates the M and E-protein heterotetramer, 2JLV (Luo *et al.*, 2008) which represents the NS3 protein (serine protease as well as RNA helicase and RTPase/NTPase) and 4C11 showing the NS5 protein were downloaded from the Research Collaborator for Structural Bioinformatics (RCSB) protein data bank and visualized using YASARA (Krieger *et al.*, 2002). Changes to protein stability were estimated using Fold-X (Schymkowitz *et al.*, 2005).

Statistical analysis: The correlation between the diversity of epidemic lineage and transmission intensity, are compared with the number of DENV-1 genotype III variants against the total number of DENV-1 cases and total number of reported cases on a monthly basis (November 2012 to May 2014). The strength of correlation was quantified using Pearson's correlation coefficient in 'R' package.

Results: DENV-1 genotype III strains of the epidemic lineage were first detected locally in November 2012. The genetic distinction of the epidemic lineage from the locally circulating DENV-1 strains indicated that its emergence in Singapore was likely to be due to an introduction. The resulting mutant diversity intensified during periods of high transmission, implying a relationship between the force of *in-situ* evolution and transmission intensity during the epidemic. Tracking genetic diversity through time is a useful tool to infer DENV transmission dynamics and to complement surveillance data in a risk assessment and cross-sectional surveys and longitudinal virus surveillance efforts with limited sample sizes tend to underestimate the true diversity of viral populations.

Epidemic Resurgence of Dengue Fever in Singapore in 2013–2014: A Virological and Entomological Perspective (Hapuarachchi *et al.*, 2016b)

Case burden of the dengue epidemic in 2013 and 2014 was unprecedented, recording 1.7 times more cases than those reported during the last DENV-1 epidemic during 2004–05. The epidemic is due to demographic, social, virological, entomological, immunological, climatic and ecological factors that contribute to DENV transmission.

Epidemic: The control of vector-borne dengue in Singapore is carried out by National Environmental Agency which manages the day-to-day vector control and Clinical management and surveillance is overseen by Ministry of Health (Ng and Vythilingum, 2011). NEA and MOH jointly perform the below activities to manage the epidemic crisis at Singapore:

1. Enhanced case surveillance measures to increase the diagnostic coverage at the very early phase of the epidemic. MOH initiates high clinical suspicion of dengue among febrile cases and existing network of general practitioners was encouraged to utilize a subsidized laboratory testing service provided by EHI, one of the public health laboratories under NEA, Singapore.
2. Projection of case numbers to facilitate stockpiling of diagnostic reagents in advance to tackle a sudden endemic of dengue. Statistical models are used on weekly case numbers (Shi *et al.*, 2016) arrangements were made to extend EHI diagnostic services during weekends and to stockpile diagnostic reagents several months ahead of the peak of the epidemic. The close communication between MOH and NEA on the weekly case projection also allowed hospitals to plan for increased demand on the healthcare system resulting from extra consultations and admissions.
3. Expansion of virus surveillance was extended to include samples from polyclinics, hospitals and private laboratories through a joint initiative between NEA and MOH. Even during non-epidemic periods, joint efforts are thrown to screen a small proportion of reported cases to have regular surveillances. Serotype analysis was achieved in 33% of reported cases and genotype coverage was doubled during 2013–14. Genetic fingerprinting of virus strains allowed monitoring of their spread between locations and facilitated targeted vector control in newly-introduced sites.
4. Early launch of the dengue campaign was a key success to promote community awareness on dengue. NEA launched "Do the Mozzie Wipe-out" drive at clustered housing estates b street banners and social media. A tri-colour coded banner (Green: no dengue; Yellow: cluster with less than 10 cases; Red: cluster with more than 10 cases) was introduced to make public to have an immediate knowledge on their sector. Dengue volunteers are trained to support community outreach through seminars, talks, roadshows and media.
5. Enhanced source reduction for mosquito breeding is achieved by increased premises inspections, entomological surveillance, enforcement activities, and daily checks on common ground areas, public areas and congregation areas for potential mosquito breeding spots. Chemical larviciding activities were carried out in housing estates, industrial premises and public places on a regular basis and whenever *Aedes* breeding was detected through inspections. The public was encouraged to use pellets containing *Bacillus thuringiensis* in places such as roof gutters. Fogging activities were conducted in major clusters during the peak periods of transmission to reduce adult *Aedes* population density especially when the intensity of transmission sustained

despite other source reduction efforts. Data on *Aedes* immatures collected through field inspections was used to gauge *Aedes* population density in a particular area.

6. Launch of gravidtrap is a greater milestone in detecting and monitoring adult *Aedes* population and viral carriers in any area. The breeding data collected on a regular basis from sentinel locations and gravidtrap and are matched with cluster locations.
7. Spatial risk map is drawn based on data pertaining to *Aedes* breeding, past dengue exposure, population density, and circulation virus strains and is used as a guide for resource allocation during epidemic.
8. Integrated vector management activities in Singapore are closely aligned with the whole-of-government's effort in establishing people, public and private (3P) partnership to develop innovative and sustainable initiatives to promote environmental ownership in the community. NEA leads an Inter-Agency Dengue Task Force (Koh *et al.*, 2008) comprising 27 stakeholders from the 3P sectors to coordinate nationwide dengue control efforts. The Inter-Agency Dengue Task Force assisted the epidemic control by ensuring the planning and implementation of operational activities of each agency to align with source reduction and vector control efforts carried out by NEA.

The integrated surveillance framework is supported by Improved operational response; Early warning of outbreaks based on virus surveillance; Understanding the distribution of vectors and their density fluctuations through entomological surveillance; Understanding the relationship between environmental parameters and outbreak risk.

Discussion

The spread and prevalence of dengue and dengue fever are better understood through region-wide synchrony, travelling waves, dengue forecast models, evolutionary studies, and epidemic resurgence.

In this short review, we have briefed studies that were conducted in and around Singapore. These countries (Thailand, Singapore, Malaysia) notice a huge human traffic cross bordering each and every day. The patterns from these studies caution authorities to monitor the spread across these countries in this region. An epidemiological study to understand the virus resurgence can't be successfully performed without inherent data from nearby countries and disease population data. A multi-level approach involving epidemiological, virological and entomological is required in a combined population across nations.

Background/Fundamentals

Modern genome biology relies on the inference of homology from protein and DNA sequence similarity searching. As the number of sequenced genomes has grown from the dozens to the thousands and tens of thousands today, except for a small number of experimental model organisms, most functional annotations on newly sequenced genomes are transferred based on similarity searches. This section examines the philosophical and statistical basis for inferring homology from excess similarity.

The inference of homology – common evolutionary ancestry – is a conclusion about relationships based on biological events that often occurred from 0.5 to 3 billion years ago. For example, based on excess protein sequence similarity, about 40% of human enzymes have easily identified homologs in *E. coli* (Fig. 1). This observation of excess similarity implies that large fraction of human and *E. coli* proteins existed more than 3 billion years ago in the organism that was the last common ancestor of mammals and bacteria. And 40% is a very conservative estimate; it is likely that a much larger fraction of human enzymes have homologs in *E. coli*, but 40% are easily detected in a BLASTP search.

The ability to identify such distant homologs was unexpected. In the late 1960s, as the first protein sequences became available, one of the first uses of “homology” to denote excess similarity (Winter *et al.*, 1968) explicitly denied that the traditional evolutionary meaning of the word (common ancestry) was appropriate in the protein context, suggesting that excess similarity might be the result of very similar protein sequences emerging independently, analogous to the emergence of the ability to fly in insects and vertebrates. But this argument was short-lived, as early researchers came to understand that the space of possible protein sequences is astronomically large (McLachlan, 1971; Altschul *et al.*, 1994). Thus, faced with the two logical alternatives for excess similarity – common ancestry or independent origins – the more parsimonious explanation, in the presence of excess similarity, is common ancestry.

The “homology:excess similarity” relationship is also confused by the use of the term “homology” in place of “identity,” as in the phrase “these sequences are 30% homologous.” Because homology is a qualitative inference, two proteins are either homologous, or they are not homologs (Reeck *et al.*, 1987). Homology and identity are not interchangeable; homology is a *qualitative* statement about evolutionary ancestry, while identity is a *quantitative* statement about sequence similarity. While sequence identity can be a

Fig. 1 Sensitivity of protein and DNA sequence comparison – One hundred human RefSeq proteins and their corresponding mRNA sequences from proteins with E.C. numbers (enzymes) were compared to proteomes and mRNA sequence sets from the indicated genomes. Plotted are the number of queries that had at least one homolog with enough excess similarity that the score would be expected in fewer than 1000 searches by chance ($E < 0.001$) in searches against the indicated proteomes/RNA-sets using SSEARCH and BLASTP for protein:protein comparisons, FASTX and BLASTX for DNA:protein comparisons, and BLASTN for DNA:DNA comparisons. Divergence times from timetree.org.

reliable (though insensitive) measure of excess similarity, and identity is a useful indicator of evolutionary distance (homologous sequences that are 90% identical are much more closely related than sequences that are 30% identical), identity (or similarity) and homology are fundamentally different concepts. Amino-acid residues can be homologous (share a common evolutionary history) without being identical, and residues may be identical simply by chance (thus not sharing common ancestry).

Homology inference is often based on excess pair-wise sequence similarity found in a similarity search, using a program like BLASTP (Altschul *et al.*, 1990; Altschul *et al.*, 1997; Camacho *et al.*, 2009). Pair-wise sequence similarity is effective because modern sequence databases are comprehensive – complete proteomes are known for thousands of organisms. However, pair-wise sequence comparison is less sensitive than comparison based on excess structural similarity (Pearson and Sierk, 2005). Excess structural similarity is considered the “gold standard” for inferring homology, but the argument for homology from excess similarity is the same. If two structures share much more similarity than is expected by chance, the simplest explanation is that the excess similarity reflects common ancestry. Methods to improve sequence-based homology inference often rely on homology inferences based on excess structural similarity. While structure comparison is far more sensitive than pair-wise sequence comparison, only a fraction of protein sequences are homologous to proteins with known structures. Because there are so many complete proteomes, sequence comparison can be used to identify homologs for almost every protein in a newly sequenced genome.

Intermediate in sensitivity between pair-wise sequence comparison and pair-wise structure comparison are sequence based methods that use sequence models, using either Position-Specific Scoring Matrices (PSSMs, Altschul *et al.*, 1997; Schaffer *et al.*, 2001; Altschul and Koonin, 1998), or Hidden Markov Models (HMMs, Sonnhammer *et al.*, 1998; Finn *et al.*, 2011; Eddy, 2011). Model-based methods (PSSMs, HMMs) can be 5–10-fold more sensitive than pair-wise alignment (Pearson *et al.*, 2017). Model-based methods provide an automated approach to transitive similarity searching – if A shares significant similarity with B, and B with C, then A can be inferred to be homologous to C without sharing significant pair-wise similarity (Gerstein, 1998).

Application

The inference of homology from excess similarity requires both (1) algorithms to align sequences and produce similarity scores and (2) an accurate model of how much similarity is expected by chance. The first algorithm used to align protein sequences (Needleman and Wunsch, 1970) produced a *global* sequence alignment – sequences were aligned from end-to-end – and accommodated a variety of match/mismatch penalties, from simple identities to more sophisticated measures of amino-acid similarity. The Needleman-Wunsch algorithm used a penalty-*per-gap* strategy; a gap of one residue, or two, or five would all have the same cost.

Today, most similarity searching programs, including BLAST, calculate a local alignment score – one in which the alignment can begin and end anywhere in the sequences as long as it produces a maximum score. Local alignments can identify homologous domains in different sequence contexts, and work well with partial protein sequences produced by exons in genome assemblies. The first rigorous local alignment algorithm was described by Smith and Waterman (1981). Modern algorithms use a more efficient form described by Gotoh (1982), vectorized versions of the rigorous Smith-Waterman-Gotoh local alignment algorithm (Farrar, 2007) can speed searches 10–20-fold.

In addition to an algorithm to calculate alignment scores, homology inference requires an understanding of alignment score statistics. To recognize *excess* similarity, it is critical to understand how much similarity is expected by chance (between random or unrelated sequences), particularly in the context of a database search, where tens of thousands to tens of millions of sequences are compared. Early protein sequence analysts understood the importance of evaluating statistical significance using unrelated (typically shuffled) sequences (McLachlan, 1971), but without a statistical model of the distribution of unrelated scores, it was impossible to accurately estimate probabilities. The recognition that local similarity scores between random protein or DNA sequences are accurately described by the extreme-value distribution (Arratia *et al.*, 1986; Karlin and Altschul, 1990), even for gapped alignments (Mott and Tribe, 1999), allows excess similarity to be measured and thus homology to be identified routinely. These statistical foundations enabled the BLAST programs (Altschul *et al.*, 1990, 1997) to provide the first accurate statistical estimates for similarity scores. Today, all widely-used similarity search programs provide accurate statistical estimates (Brenner *et al.*, 1998; Pearson and Sierk, 2005).

The most widely used sequence comparison algorithm, BLAST (Altschul *et al.*, 1990, 1997; Camacho *et al.*, 2009), uses the Karlin and Altschul statistical model (Karlin and Altschul, 1990) to set heuristic thresholds for the inclusion of *k*-letter amino-acid “words” (typically *k*=3 for proteins) to dramatically accelerate sequence comparison by not examining alignments that are unlikely to reflect homology. Since homologous sequences are rarely more than 1.0% of a comprehensive sequence database (in the human proteome, only 6 of 6116 Pfam domain families are present in more than 1.0% of proteins, with the most abundant domains, protein kinases and Zn-fingers, appearing in 2% of proteins), focusing on sequences that could produce significant alignments can speed up similarity searches 100-fold.

Local sequence alignment scores between random sequences are well described by the extreme value distribution:

$$p(S_{\text{raw}}) \leq 1 - \exp(-Kmn e^{-\lambda S_{\text{raw}}}) \quad (1)$$

where S_{raw} is the calculated alignment score, m, n are the lengths of the two sequences being aligned, λ is a parameter that captures the “scaling” of the scoring matrix used to produce the alignment score, and K is a parameter that captures how the similarity scores of random sequence alignments increase with sequence length. For alignment scores with $p < 0.1$, this equation can be simplified to:

$$p(S_{\text{raw}}) \leq K m n e^{-\lambda S_{\text{raw}}} \quad (2)$$

which can also be expressed in terms of a “bit” score as

$$p(S_{\text{bits}}) \leq m n 2^{-S_{\text{bits}}} \quad (3)$$

where $S_{\text{bits}} = (\lambda S_{\text{raw}} - \ln(K)) / \ln(2)$

The “bit” score has the advantage that Eq. (3) can be used to calculate the probability of any S_{bit} score, regardless of the scoring matrix, and “bit” scores are available for most similarity searching programs (BLASTP, [Camacho et al., 2009](#); FASTA, [Pearson, 2016](#)); and HMMER3, [Eddy, 2011](#)).

The $p(S)$ value calculated in Eqs. (1)–(3) reflects the probability of obtaining a score $\geq S$, in a *single* sequence alignment between two unrelated proteins. Because it assumes that only one alignment score has been calculated, $p(S)$ is not the appropriate measure of statistical significance in a similarity search of a protein or DNA database, where hundreds of thousands to tens of millions of sequences have been examined. To account for the thousands to millions of multiple tests (alignments) that were considered in a search, the p -value is converted to an expectation value using a Bonferroni correction:

$$E(S) \leq p(S) D \quad (4)$$

where D is the number of alignments performed. Equivalently:

$$E(S_{\text{bit}}) \leq D m n 2^{-S_{\text{bit}}} \quad (5)$$

or, for BLAST where the length of the database is: $N = Dn$

$$E(S_{\text{bit}}) \leq m N 2^{-S_{\text{bit}}} \quad (6)$$

Because the Bonferroni correction (Eqs. (4)–(6)) changes the expectation value depending on the size of the database (the number of comparisons, or tests), the same similarity score can be statistically significant in some contexts (e.g., a single proteome with 20,000 sequences) but not in others (e.g., comprehensive protein databases with tens of millions of sequences). For example, alignment of human RefSeq protein NP_000444 (a sodium/iodide cotransporter, 643 amino acids) with *E. coli* NP_418491 (an acetate transporter, 549 amino acids) produces a local alignment score of 45 bits. If the *E. coli* sequence had been identified in a search of human proteins ($\sim 40,000$ sequences), the relationship would be statistically significant, with $E(S_{\text{bits}} = 45, D = 40,000) \leq 40,000 \times 643 \times 549 \times 2^{-45} = 4.2 \times 10^{-4}$. In contrast, the same alignment would not be significant if the *E. coli* protein had been compared to UniProt ($\sim 40,000,000$ sequences, $E() \leq 0.42$) or RefSeq ($\sim 80,000,000$ sequences, $E() \leq 0.84$).

This loss of statistical significance with increased database size can be disconcerting, because it suggests that two sequences can be homologous in searches of small proteome databases but not in searches of large comprehensive sequence sets. The discrepancy highlights the fundamental asymmetry when inferring homology using statistical significance; a *significant* similarity score *can* be used to *infer* homology, but a *non-significant* similarity score *cannot* be used to infer *non-homology*.

In this example, the alignment does reflect homology; both proteins contain a sodium:solute symporter family domain (PF00074, [Finn et al., 2016](#)) but the alignment score (45 bits) is not large enough to guarantee statistical significance after the Bonferroni correction for large datasets. In databases with tens of millions of sequences, a score of 45 bits will often occur by chance.

The relationship between database size and homology inference is key to interpreting similarity search results. Homology inference is asymmetrical; sequences that share statistically significant similarity can be reliably inferred to be homologous, and non-homologous sequences should never share statistically significant similarity after the significance has been corrected for multiple testing, but sequences that do not share significant similarity are not always non-homologous.

The expectation value $E(D)$ reports the number of times (on average) that an alignment score would be expected by chance in a database of D unrelated sequences. Thus, an alignment with an $E()$ -value of 0.001 would be expected to occur by chance once in 1000 searches of the database. $E() \leq 0.001$ is frequently used to infer homology in a single similarity search (but it *cannot* be used to infer non-homology). As the example shows, there may be more distantly related homologs with $E()$ -values ~ 1 or even higher, mixed among alignments of unrelated sequences with $E() \sim 1$.

The relationship between bit scores and statistical significance (Eqs. (4)–(6)) can be used to calculate the minimum bit score that would be statistically significant in searches of databases with different numbers of sequences. For average length proteins (400 amino-acids), to achieve $E() \leq 0.001$, a score of:

$$0.001 \leq D \times 400 \times 400 \times 2^{-S_{\text{bits}}} \quad (7)$$

$$D \geq 0.001 / (400 \times 400 \times 2^{-S_{\text{bits}}}) \quad (8)$$

$$160,000 \times D / 0.001 \leq 2^{S_{\text{bits}}} \quad (9)$$

the $-S_{\text{bits}}$ exponent is inverted

$$\log_2(160,000,000 \times D) \leq S_{\text{bits}} \quad (10)$$

$$27.25 + \log_2(D) \leq S_{\text{bits}} \quad (11)$$

For *E. coli*, $\log_2(4000) = 12$ so a 40-bit score is significant ($E(S_{\text{bit}} = 40, D = 4000) < 0.001$); for human $\log_2(40,000) \simeq 15$, so 43 bits are required. For large protein databases like UniProt ($\log_2(40 \times 10^6) \simeq 25$), so ~ 50 –55 bits are required for statistical significance.

Protein sequence similarity searching can routinely identify homologs – proteins sharing a common ancestor – that diverged > 2 billion years ago, using a single protein query sequence. More sophisticated methods, such as PSI-BLAST (Altschul *et al.*, 1997) and HMMER3/jackhmmmer (Eddy, 2011) are dramatically more sensitive. These approaches build an ancestral model of a protein family or domain that typically can identify 5–10 times as many homologs as a single sequence BLASTP search. For PSI-BLAST, this model is a Position Specific Scoring Matrix (PSSM) that captures the specific sequence changes possible at each residue across the length of the protein or domain. HMMER3/jackhmmmer uses a more sophisticated approach to build a Hidden Markov Model (HMM) that captures both the substitution frequencies at each position across the model and the variation in gap-frequency at different locations. However, despite their much higher sensitivity compared with pairwise-sequence comparison, PSI-BLAST and HMMER3 can also fail to identify distant homologs that can be identified using structure comparison (Pearson and Sierk, 2005). Today, there is no sequence-based method that is as sensitive as structure comparison, though methods that use HMM-HMM comparison approach this ideal (Sadreyev *et al.*, 2003; Remmert *et al.*, 2012).

Case Studies

The discussion above has focused on the inference of homology from protein sequence comparison. Protein sequence comparison provides dramatically greater evolutionary look-back time than DNA sequence comparison for several reasons: (1) protein sequences change more slowly than DNA sequences, because many DNA changes are silent – they do not change the encoded amino acid; (2) protein sequence comparison can take advantage of an informative scoring matrix, e.g., the BLO-SUM62 matrix gives similar, but non-identical (e.g., arginine, lysine, histidine, or leucine, isoleucine, and valine) positive alignment scores, and gives amino-acids that are rarely substituted negative scores; (3) the amino-acid alphabet is larger (20 vs 4 residues), so chance alignments between protein sequences occur at much lower percent identity; (4) protein sequence databases are much smaller than DNA sequence databases, since 95% or more of metazoan genomes do not code for protein; and (5) while unrelated protein sequences are indistinguishable from random protein sequences, unrelated DNA sequences can have local composition and other biases that make it difficult to produce random DNA sequences that look like real, unrelated DNA sequences. As a result, while expectation values with $E() < 0.001$ will occur by chance once in 1000 searches for protein sequences (Pearson and Sierk, 2005), they occur much more often in DNA sequences, so $E() < 10^{-10}$ is often used as a threshold for inferring homology with DNA:DNA comparison.

The dramatic difference in sensitivity between protein and DNA comparison is illustrated in Fig. 1, which shows how the sensitivity of sequence similarity searches drops with evolutionary distance, using protein:protein, DNA:protein, and DNA:DNA comparisons. The figure illustrates that protein:protein (SSEARCH, BLASTP) and translated-DNA:protein (FASTX, BLASTX) can identify homologs in 99%–100% of the queries among the vertebrates (500 Mya), in more than 95% of the queries among metazoa (800 Mya), in more than 80% of queries between humans and plants (1500 Mya), and in ~40% of queries between humans and *E. coli*. Moreover, there is relatively little loss in sensitivity with translated-DNA:protein vs protein:protein alignments. In contrast, while DNA:DNA searches (BLASTN) can find homologs for 93% of the queries between human and mouse (and this number is high because the DNA sequences encode protein; non-coding sensitivity would be much lower), comparison of human queries find homologs for only 15% of queries in fish, and less than 5% of queries between humans and *Drosophila*. Protein:protein and translated-DNA:protein comparisons allow homologs to be identified 10-times earlier in evolutionary time than DNA:DNA comparisons.

Discussion

The identification of biological homologs – genes, protein sequences, or protein structures that share a common ancestor – is based on the parsimonious principle that when sequences or structures share much more similarity than is expected by chance, the simplest explanation for the excess similarity is common ancestry, i.e., the sequences are similar because they are descendants (copies) of an ancient protein. Thus, the ability to recognize distant homologs depends both on a method to calculate a similarity score, e.g., BLASTP (Camacho *et al.*, 2009) or FASTA (Pearson, 2016), and an accurate model of the amount of similarity expected by chance. Today, because there are so many fully sequenced genomes and their corresponding proteomes, virtually every similarity search identifies hundreds if not thousands of homologs. But pair-wise similarity searches sometimes miss large numbers of homologs that can be detected by transitive similarity searches, model based methods (PSI-BLAST, HMMER3), and structure comparison. As a result, even the most sensitive sequence based similarity searches miss distant homologs. Despite its imperfections, homology inference from excess sequence similarity is the most powerful and reliable strategy for characterizing new protein and DNA sequences, and is most effective when comparisons use protein sequence databases.

Introduction

Just as species show differences in their morphology, ecology, and behavior, they also show differences in their DNA sequences (Wilson *et al.*, 2017). “DNA barcoding,” used in a broad sense, refers to the use of short, standardized DNA sequences as markers for the recognition of species. When used more precisely, “DNA barcoding” refers to the technique of sequencing a short fragment of the DNA sequence of the mitochondrial cytochrome c oxidase subunit I (COI) gene, the animal “DNA barcode,” from a taxonomically unknown specimen and performing comparisons with a library of DNA barcodes from taxonomically known specimens to establish a taxonomic identification.

DNA barcoding requires basic molecular biology methods (which pre-date the term DNA barcoding) to extract and amplify the DNA barcode sequence fragment from the unknown specimen (Fig. 1). Generally, this sample of amplified DNA is then passed to commercial companies for inexpensive Sanger sequencing, or, particularly in the case of mixed, bulk samples, for high-throughput (next generation) sequencing. These molecular biology methods are not covered in this article which focuses on bioinformatics workflows following the receipt of digital DNA sequences from a sequencer (Fig. 1). For a step-by-step guide to the molecular biology methods used for standard (animal) DNA barcoding see Wilson (2012) and for an approximation of costs in developing countries see Sing *et al.* (2016). Brandon-Mong *et al.* (2015) provide an example of a method (bulk extraction and bulk PCR) for use prior to high-throughput sequencing, i.e., DNA metabarcoding.

Fig. 1 The DNA barcoding workflow.

The ultimate aim of a DNA barcoding bioinformatics workflow is to (1) produce a “clean” or “reliable” digital representation of the DNA barcodes, and (2) use these DNA barcodes to obtain information about the taxonomy of the unknown specimen through algorithms enabling DNA sequence comparisons, in conjunction with DNA sequence libraries (Fig. 1).

Background/Fundamentals

It is important to realize that full exploitation of DNA barcodes for species recognition will only be possible after assembling a comprehensive library linking organisms (and Linnaean taxonomy) with their DNA barcodes (see Wilson *et al.*, 2017 for an assessment of DNA barcode library coverage for insects). With this in mind, in an effort to promote DNA barcoding research and DNA barcode library building (e.g., Wilson *et al.*, 2013), we have been organizing and facilitating DNA barcoding workshops in Southeast Asia, a mega diverse region with relatively low DNA barcode coverage in public libraries (Wilson *et al.*, 2016). We have created a website, DNA Barcoding Workshops (DBW), as a companion resource to our workshops and much of the material in this article derives from our experience running these workshops.

This article is intended as a guide for absolute beginners to DNA barcoding, and provides step-by-step instructions for basic bioinformatics workflows following receipt of DNA sequences from a DNA sequencing facility.

Application

Getting Started With DNA Barcoding: The Barcode of Life Datasystems

The Barcode of Life Datasystems (BOLD) (Ratnasingham and Hebert, 2013) is a cloud-based data storage and analysis platform developed and maintained by the Centre for Biodiversity Genomics (CBG) in Canada. It consists of four main modules, a data portal, an educational portal, a registry of Barcode Index Numbers (BINs) (putative species), and a data collection and analysis workbench. BOLD is the recommended place to manage your DNA barcoding research. Please see the BOLD Handbook available from the BOLD website (under “Resources”) and the DNA Barcoding Workshop (DBW) website for step-by-step instructions for: (i) creating an account on BOLD; (ii) preparing specimen data for BOLD; (iii) creating a project on BOLD; and (iv) adding records and images to BOLD. You will need to have completed these steps in order to upload your DNA barcode sequences to BOLD and to use the BINs system. Note that BOLD keeps all of your work (specimen records, sequences, etc.) private, accessible only to yourself and your coworkers, until you choose to make the work public.

Editing Sanger Sequences

To learn more about the process of Sanger sequencing see the resources on the DNA Learning Centre website from the Cold Spring Harbor Laboratory. The outputs of Sanger sequencers are trace files (also known as chromatograms and electropherograms), digital representations of DNA sequences. For a number of reasons, a trace may not be “clean”, it may be “messy”, and the first step is to “edit” the sequence, a process during which “messy” parts of sequence are removed and only “reliable” sequence is retained.

- a) Usually your sequences will come back from the sequencing company by email in a zip (folder) file. An example of a zip file containing 12 trace files (6 each trace files for forward and reverse) (6 unknown specimens), representing the kind of zip file you could receive from a sequencing company, is provided for download as Supplemental File 1.
- b) Unpack (extract) the zip file to your desktop. This should create a regular folder on your desktop, which you can name *Traces*. There are two sets of files for each sequence (e.g., *NUMBEROFSAMPLE_F.ab1* and *NUMBEROFSAMPLE_F.txt*). The files you are interested in have an extension .ab1 (e.g., *NUMBEROFSAMPLE_F.ab1* and *NUMBEROFSAMPLE_R.ab1*). Delete the other files in the folder.

For sequence editing we recommend the program CODONCODE ALIGNER which is used at the Canadian Centre for DNA Barcoding (CCDB). Information on CODONCODE ALIGNER, including a free trial version, can be found at the Codoncode Corporation website. The following steps describe the process of Sanger sequence editing for multiple specimens whose DNA barcodes were amplified using the primers *LCO1490* and *HCO2198* (see Wilson, 2012; Brandon-Mong *et al.*, 2015). For practice you can go through these steps using the example files in Supplemental File 1. For other primer sets adapt accordingly.

- a) Open CodonCode Aligner and choose *Create a new project* and press OK.
- b) Go to *File > Import > Add Folder...* navigate to the desktop and select the folder of traces [which should be named *Traces* if you followed the suggestion above]. Click *Open > Import*.
- c) To see the files you just imported press ► besides the *Unassembled Samples* folder.
- d) The .ab1 files should be of the form *NUMBEROFSAMPLE_F.ab1* where the second part “F” refers to the direction, i.e. Forward.
- e) Sort the files by quality by double-clicking on *Quality*. Any sequences that are of very poor quality (look for a big difference between the sequence length and the quality score; a higher quality score is better) can be deleted by highlighting the sequence and clicking *Edit > Move to Trash*.
- f) Next we will group our sequences by direction for easy editing.

- g) Make sure the *Unassembled Samples* folder is highlighted. Select the *Contig* menu and move the cursor over *Advanced Assembly*. From the options that appear select *Assemble in Groups*.
- h) A new window will appear. Click the button *Define name parts...*
- i) There are two name parts to our file names (see above). The first part of our file names refers to the number of the sample and for our purposes the option in the *Meaning* menu (first row) can be left as *Clone*. Since the sample number is followed by an underscore, choose *_ (underscore)* in the *Delimiter* menu next to *Clone* (if it is not already selected).
- j) For the second row choose *Direction* in the *Meaning* menu. We can ignore the *Delimiter* menu for the *Direction* part because there is nothing following the direction in our file names.
- k) Delete all additional name parts that may appear in the window (if any), and next click *Preview...* to check how CodonCode Aligner is interpreting the sample names.
- l) Click *Close* to exit the preview. Click *OK* to return to the *Assemble in Groups* window.
- m) We first want to assemble our samples according to direction. Choose *Direction* in the *Name part:* dropdown menu. Then click *Assemble*. You should now have two folders, one called **F** with the forward sequences and one called **R** with the reverse sequences. [Note: if you only sent your PCR products for sequencing in one direction, i.e., with one primer, then you will only have one folder.].
- n) We will deal with the reverse sequences first. The first step is to reverse complement the sequences. Highlight the **R** folder, select *Edit > Reverse complement*.
- o) Next we need to cut the primer from the sequence. Double click the **R** folder to open it. For the reverse sequences, you need to find the forward primer motif and delete it from the beginning of the consensus sequence at the bottom of the window. You will find the primer around 30 nucleotides from the end of the raw sequence. For example, you would need to delete the section of the sequence marked below in **bold** and everything to the left of it. Highlight it on the **consensus** sequence at the bottom of the window and press the **Backspace** key on the keyboard. ←AAAGATATTGGAACATTATATTATTTT...
- p) Next go to the opposite end of the consensus, the far right. Delete the consensus sequence from the point where the sequence gets messy. This will be apparent due to lots of green highlight. For example [it will not look exactly like this], delete the section marked in **bold** and everything to the right of it. Highlight it on the **consensus** sequence at the bottom of the window and press the **Delete** key on the keyboard. Close the window. ... TCITTTTTTGACCCTGCTGGTGGAGG**TTTCTAGCAGGATC**→
- q) Double click the **F** folder to open it. Go to the far right of the consensus sequence and find the reverse complement reverse primer motif at the very end. This should be around 650 bp on the raw sequence. For example, you would delete the section marked in **bold** and everything to the right of it. Highlight it on the **consensus** sequence at the bottom of the window and press the **Delete** key on the keyboard. ... CAACATTTATTTT**GCATTTTGG**→
- r) Next go to the opposite end of the consensus, the far left, and delete the consensus sequence from the point where the sequences get messy. This will be apparent due to lots of green highlight. For example [it will not look exactly like this], you would delete the sequence in **bold** and everything to the left of it. Highlight the region on the consensus sequence at the bottom of the window and press the **Backspace** key on the keyboard. Close the window. ←**ATGCTTTTTTTTKGG**TGTTTAATCAGGACTAATTGGAAC TTC
- s) Dissolve both the **F** and **R** folders by highlighting them and clicking the button marked with a red **X**.
- t) Now we are going to combine the forward and reverse sequence from each specimen into a contig. Highlight the *Unassembled Samples* folder and open the *Contig* menu. Move the cursor over *Advanced Assembly*. From the options that appear select *Assemble in Groups*. This time choose *Clone* in the *Name part:* menu, then click *Assemble*. [Note: if you only sent your PCR products for sequencing in one direction (with one primer) then you will need to check each sequence individually rather than checking a consensus (contig).][Note: specimens which only sequenced successfully in one direction will have files which remain in the *Unassembled Samples* folder.]
- u) The contigs are likely to be in reverse complement orientation. Highlight every folder (contig), select *Edit > Reverse complement*.
- v) Open each folder (contig) in turn by double-clicking. Correct ambiguous positions (shown in red, in green highlight, and/or as N) and gaps ("—") in the consensus sequence by checking the original traces. This is done by double-clicking on the **consensus sequence** at the bottom of the window. Always check both trace files (forward and reverse) and compare them. [Note: the corrected consensus sequence should have **NO** gaps.].
- w) Generally if traces conflict (i.e., different colored peaks appear in the same location on the forward and reverse chromatograms) you can decide which is more reliable based on sequence quality (e.g., less background noise, taller peaks).
- x) Check the contigs first, then check the individual single sequences in the *Unassembled Samples* folder, if any.
- y) To export the consensus sequences, highlight all the folders, go *File > Export > Consensus Sequences...*, choose *Current selection*. Open the *Options* and select *Include gaps in FASTA* but deselect all other options. Press *Export*. Save the file to the desktop as *sequences.fasta*.
- z) If necessary, to export single direction sequences, go *File > Export > Samples...*, choose *Current selection*. Press *Export*. Save the file to the desktop as *sequences_single.fasta*.

Processing High-Throughput Sequencing Reads

The files output by an Illumina MiSeq high-throughput sequencer are in FASTQ format. FASTQ is similar to FASTA but contains additional data. Note that high-throughput sequencing reads are generally demultiplexed and adapter and primer-trimmed

onboard the sequencer (e.g., onboard the MiSeq using the MiSeq Reporter software). Because the FASTQ outputs are large files, the sequencing company probably will not send the files by email but will email you a link to a website from where you can download the files, usually (like Sanger sequences), packed into a zip file. Two FASTQ files (Paired-end files) are output from each sequencing run, which you can think of as the *Forward* and *Reverse* sequences.

The following workflow describe steps taken for processing high-throughput reads for bulk arthropod samples whose DNA was amplified using the primers *mlCOIintF* and *HCO2198* (see [Brandon-Mong et al., 2015](#)). A zip file containing some example FASTQ Paired-end files are available for download as Supplemental File 2. For practice you can go through these steps using these example files. For convenience, save the files in a folder (called *Reads*) on your Desktop.

It is important to note that the steps provided below are crude methods for processing a very small number of high-throughput sequencing reads. The field of DNA metabarcoding is a relatively new field and much work is being undertaken to develop methods to reduce the number of “spurious” reads generated and retained by bioinformatics pipelines for high-throughput sequencing reads ([Brandon-Mong et al., 2015](#)) (see Future Directions below). For FASTQ files which are larger than the example provided as Supplemental File 2, CODONCODE ALIGNER is probably not a suitable program, and for beginners, it may be better to register and use applications provided on the GALAXY webserver. Considering that DNA metabarcoding is the focus of another article in this book, we do not provide additional details here.

- Open the PRINSEQ webserver ([Schmieder and Edwards, 2011](#)), click *Use PRINSEQ* and click on *Upload Data*.
- Your files are *FASTQ Paired-end* so choose that option.
- Select the two FASTQ files you have saved on your Desktop (in the *Reads* folder).
- Under *Please select the statistics you want to generate*. Choose *None* for all options then click *Continue*.
- Wait while PRINSEQ processes your data.
- Once it is finished click *Process Input Data*.
- Choose the options from [Table 1](#).
- Choose to Output the data as FASTA, *Data passing all the filters (good)*.

Table 1 Parameters used for processing high-throughput sequencer reads

<i>Program</i>	<i>Parameter</i>	<i>Option</i>
PRINSEQ	Trim #nucleotides from 5'-end	25
	Trim #nucleotides from 3'-end	25
	Trim ends by quality scores	While Mean of scores is < (less then) 10 (5'-end) and 10 (3'-end_ using window size of 5 with step size 5
	Trim poly-A/T tails from 5'-end	That are equal to or longer than 5
	Trim poly-A/T tails from 3'-end	That are equal to or longer than 5
	Minimum sequence length in bp	200
	Maximum sequence length in bp	300
	Minimum mean quality score	32
	Minimum GC content in %	25
	Maximum GC content in %	35
	Maximum allowed rate of Ns in %	0
	Maximum number of allowed Ns	0
	Remove sequences with characters other than A, C, G, T or N	Yes
	Low-complexity threshold	80 (using Entropy)
	Dereplicate data	Remove exact sequence duplicates, Remove 5' sequence duplicates, Remove 3' sequence duplicates, Remove reverse complement exact sequence duplicates, Remove reverse complement 5'/3' sequence duplicates
CODONCODE ALIGNER	Algorithm	Local alignments
	Min. percent identity	97.5
	Min overlap length	20
	Min score	20
	Max. unaligned end overlap	100.00
	Bandwidth (max. gap size)	30
	Word length	10
	Max successive failures	50
	Match score	1
	Mismatch penalty	− 2
	Gap penalty	− 2
	Additional first gap penalty	− 3

- i) Click *Generate Files*.
- j) Use right click on the file you want (all of the FASTA files) to download and select “Save Link As” to save the file into a folder on your Desktop (which you could name *Filtered Reads*).
- k) Next we will be using CODONCODE ALIGNER (see above). Go to *File > Import > Add Folder...* Import the sequences in the FASTA files in the *Filtered Reads* folder. Click *Rename Duplicates*.
- l) Select all the sequences and click *Assemble*. Make sure the settings for *Assembly* found under *Edit > Preferences* are set to match those in [Table 1](#).
- m) Select all the contigs, including the *Unassembled Samples* folder and again, *Assemble*. Repeat until the number of contigs cannot be reduced any further.
- n) Delete (*Move to Trash*) the sequences still remaining in the *Unassembled Samples* folder.
- o) Export all the remaining contigs as consensus sequences (FASTA file), highlight all the folders, go *File > Export > Consensus Sequences...*, choose *Current selection*. Make sure none of the *Options* are selected.

Sequence Alignment

The alignment of DNA barcode sequences is a necessary step before two or more DNA barcode sequences can be compared with one another. Sequence alignment is the process of lining up nucleotides which are assumed to have the same common ancestor (i.e., thought to be homologous). BIOEDIT is the most commonly used program for small-scale sequence alignment, and is free for use by any and all interested parties. BIOEDIT can be downloaded from the program website but is no longer being regularly maintained.

- a) Open your FASTA file (e.g., *sequences.fasta*) in BIOEDIT.
- b) If necessary, you can then use *File > Import > Sequence alignment file* to add additional sequences (e.g., *sequences_single.fasta*) to the alignment.
- c) Make sure *Mode*: is set to *Edit* using the dropdown menu.
- d) Another dropdown menu will become visible to the right of the *Edit* dropdown. Make sure this is set to *Insert*.
- e) Sequences that have ended up in the FASTA file in the wrong orientation (with standard primers, full length arthropod DNA barcodes should typically start AAC or TAC) may be corrected by highlighting the sequence name by clicking the cursor on it, clicking the *Sequences* menu at the top of the screen. Moving the cursor down the dropdown to *Nucleic Acid* and clicking *Reverse complement*.
- f) Sequences all need to be the same length (typically 658 bp for full length DNA barcodes; 300 bp for metabarcodes) and aligned to each other (before proceeding for further analysis or before uploading to BOLD and GenBank). This can be done by typing additional *N(s)* at the beginning and end of the sequences in the *Edit* mode. Be sure to check across the whole of the alignment of the sequences that you have added the correct number of *N(s)*.
- g) In [Fig. 2](#) featuring a 50-bp barcode for simplification, *JKN001-17* is of full length. *JKN002-17* needs 6 *Ns* adding to the left side of the sequence to become aligned, while *JKN003-17* needs 4 *Ns* adding to the right side of the sequence to be 50 bps long. *JKN005-17_F* needs to be reverse complemented to be in the same orientation as the other sequences.
- h) Sanger sequences which were not part of a consensus (i.e., when one direction failed but the single sequence is of sufficient length and quality for submission to BOLD) may appear in the FASTA still tagged with the direction. This needs to be deleted, e.g., the sequence named *JKN005-17_F* should be renamed as *JKN005-17*.
- i) If you are having trouble with the alignment, a good quality (i.e., 658[0n]) sequence can be downloaded from BOLD and imported into your alignment file as a guide, e.g., *MHAHC824-05* ([Fig. 2](#)). Be sure to delete this sequence before saving the file.
- j) Save the file (*File > Save*) (e.g., save as *sequences_aligned.fasta*).

Following these steps you can upload your FASTA file (i.e., *sequences_aligned.fasta*) (and Sanger sequence trace files) to your project on BOLD. Step-by-step instruction can be found on the DBW website. Once sequences are registered in BOLD, they can also be submitted to GenBank using the *Submit to GenBank* option under the *Publication* tab on the BOLD project console.

Assigning Taxonomic Names to DNA Barcodes

For the assignment of taxonomic names to DNA barcodes (and by extension, checking sequences for contamination) we find it is best to use online tools to ensure you are searching the most recent DNA barcode library available (the DNA barcode library is constantly growing; [Wilson et al., 2017](#)). For checking DNA barcodes for contamination and/or establishing a taxonomic identity, we would commonly “blast” our DNA barcodes against the BOLD and GenBank libraries. By statistically assessing how well library and query (unknown) DNA barcodes match, we can infer homology and transfer information (such as putative species membership) to the unknown specimen.

When there are no species-level matches in the libraries, some Linnaean taxonomic information may still be retrievable. [Wilson et al. \(2011\)](#) performed an investigation of the possibilities of assigning DNA barcodes to higher taxonomic groups (genus, family) when no species matches (i.e., with > 98% similarity) are available in the library. Based on those results we suggest using a strict tree-based approach. BOLD can provide a Neighbor-Joining tree containing the query DNA barcode and the top matches by clicking *Tree Based Identification* on the *Specimen Identification Request* page (see below).

Contig

```
JKN001-17_F  AACTNTATATTTTATTTTGGAAATTTGACCAGGAATAGTAGGAACCTCTT (Forward)
JKN001-17_R  AACTTTATATTTTATTTTGGAAATTTGACCAGGAATAGTAGGAACCTCTN (Reverse)
JKN001-17    AACTTTATATTTTATTTTGGAAATTTGACCAGGAATAGTAGGAACCTCTT (Consensus)
```

[A contig is two or more sequences grouped together in the same folder, usually one Forward and one Reverse, to produce a Consensus. Note: N = A, T, C, or G]

Unaligned FASTA (BIOEDIT) (*sequences.fasta*)

Fig. 2 Examples of DNA sequences viewed in BIOEDIT and MS WORD.

BOLD identification engine

- Open your aligned FASTA file (i.e., *sequences_aligned.fasta*) in MS WORD using right click *Open with*. Select *All* of the text and *Copy*.
- Click *IDENTIFICATION* on the BOLD homepage, select *All Barcode Records On BOLD*, paste the text from your FASTA file (i.e., *sequences_aligned.fasta*) into the box *Enter sequences in fasta format*.
- BOLD was designed specifically for DNA barcoding, so the *Specimen Identification Request* page displays a list of library records and their similarity to the query (i.e., the DNA barcode of the unknown specimen). A self-explanatory *Identification Summary* is also provided. An example of a BOLD search result is shown in [Fig. 3\(a\)](#) where the sequence can be conclusively identified as *Amauthuxidia amythaon*.

GenBank BLAST

- Click *Nucleotide BLAST* on the BLAST homepage, paste the text from your FASTA file into the box *Enter accession number(s), gi(s), or FASTA sequence(s)*, and make sure the *Database* selection is *Others*.
- BLAST pre-dates DNA barcoding, and is used for a variety of purposes, so the output is a little more difficult to interpret. Like BOLD, a list of library records is displayed, generally with the closest matching library sequence (i.e., the highest % *Identity*) at the top. Four other statistics are supplied: *Max score* indicates the highest alignment score (bit-score) between the query DNA barcode and the library sequence segment (the higher the better, 1000 is very good); *Total score* and *Query coverage* are generally not applicable for protein-coding genes such as the animal DNA barcode; *E-value* is the most important statistic for DNA barcoding and indicates number of alignments expected by chance with a particular score or higher (the closer to 0 the better). An example of a BLAST search result is shown in [Fig. 3\(b\)](#) where the sequence can be conclusively identified as *Amauthuxidia amythaon*.

Fig. 3 Examples of the results of sequence identification requests using (a) BOLD identification engine and (b) GenBank BLAST.

Clustering DNA Barcodes Into Operational Taxonomic Units

Due to the incompleteness of DNA barcode reference libraries, and inconsistencies in the use of Linnaean names, besides assigning Linnaean taxonomy to DNA barcodes, it is also valuable and common practice to cluster DNA barcodes into Operational Taxonomic Units (OTU) (see [Sukantamala et al., 2017](#); [Casas et al., 2017](#)). OTU are groupings of similar sequences which are objective, operational, “species”-level units ([Ratnasingham and Hebert, 2013](#)). Several methods are available for clustering DNA barcodes into OTU and we provide step-by-step instructions for the most commonly used and easily accessible programs in this article.

BOLD Barcode Index Number system

DNA barcodes of a minimal length (200 bp) and quality (maximum proportion of Ns) requirement are automatically clustered into OTU known as Barcode Index Numbers (BINs) upon upload to BOLD. Such clusters, produced by refine single linkage analysis across the entire BOLD library have been shown to closely correspond to species recognized through traditional taxonomic approaches (i.e., morphology). Consequently, the alphanumeric identifiers can act as surrogate taxonomic names in the absence of full Linnaean assignments ([Wilson et al., 2016](#)).

Automatic Barcode Gap Discovery

Another popular tool to cluster DNA barcodes into OTU is Automatic Barcode Gap Discovery (ABGD) (Puillandre *et al.*, 2012). ABGD uses an automatic recursive procedure to converge on the best patterns for the dataset and clusters DNA barcodes into groups accordingly. The median number of ABDG groups can be used as the basis for OTU as this has produced good correspondence with traditional species in empirical studies. ABGD is available as a web interface.

- a) From the ABGD homepage click *Take me to ABGD Web site*.
- b) Open your aligned FASTA file (i.e., *sequences_aligned.fasta*) in MS WORD (using right click *Open with*), then copy and paste the DNA barcodes into the *Or paste your data (FASTA alignment) here* box.
- c) Change the *X (relative gap width)*: to 1, but keep all other settings as default.
- d) Click *Go* and then click to see the results.
- e) On the graph click the datapoint representing the median number of groups. If available choose the Recursive partition, rather than the Initial partition.
- f) The page that opens shows a list of groups and the DNA barcodes contained within them.

Neighbor-Joining in MEGA

Molecular Evolutionary Genetics Analysis (MEGA) program is an extremely popular program for tree-building and is free to download from the program website (Tamura *et al.*, 2013). Once a Neighbor-Joining (NJ) tree has been built, DNA barcodes can be sorted to OTU ad hoc based on the tree branching pattern (topology) and branch lengths (see the NJ tree and discussion in Sukantamala *et al.*, 2017). Note that NJ trees are not technically “phylogenetic” trees. Phylogenetic trees are constructed on the basis of synapomorphies, whereas NJ trees are phenetic trees, constructed on the basis of sequence similarity. DNA barcoding is concerned with relationships amongst sequences at the “species” boundary and not the reconstruction of phylogeny, so generally NJ trees are sufficient for the analysis of DNA barcodes.

- a) Start MEGA by double-clicking on the MEGA desktop icon.
- b) You can then choose *File > Open A File/Session...* > Select your FASTA file (i.e., *sequences_aligned.fasta*) from your Desktop > *Open > Analyze > Nucleotide Sequences > OK > Yes > Invertebrate Mitochondrial > OK*.
- c) You can then choose *Phylogeny > Construct/Test Neighbor-Joining Tree...* > *Yes*.
- d) In the *Analysis Preferences* window *Options Summary* tab choose the options: *Substitutions Type: Nucleotide; Model/Method: p-distance; Substitutions to Include: d. Transitions + Transversions; Gaps/Missing Data Treatment: Pairwise deletion*.
- e) Click *Compute* to accept the defaults for the rest of the options and begin the computations. A progress indicator will appear briefly before the tree displays in the *Tree Explorer*.
- f) The tree can then be exported as a Newick (text) file (e.g., *tree.nwk*) *File > Export Current Tree (Newick)*.
- g) To select a branch, click on it with the left mouse button. If you click on a branch with the right mouse button, you will get a small options menu that will let you flip the branch and perform various other operations on it. To edit the taxon labels, double click on them.
- h) Change the branch style by using *View > Tree/Branch Style*.
- i) Select *View > Topology Only* to display the branching pattern (without actual branch lengths on the screen).
- j) Edit your tree to create the image that you want to use in your publication or report. The tree can then be exported as an image *Image > Save as PDF file* or *Image > Save as PNG file*.

Bayesian Poisson Tree Processes

A Bayesian implementation of the Poisson Tree Processes (bPTP) (Zhang *et al.*, 2013) program for generating OTU is available through a web interface. bPTP can be used to delimit phylogenetic species in a similar way to the popular and widely used General Mixed Yule Coalescent (GMYC) approach (Pons *et al.*, 2006), but without the requirement for an ultrametric tree.

- a) From the bPTP homepage, click the *Browse...* button to locate and upload your NJ tree (select the Newick file, e.g., *tree.nwk*, not the image file).
- b) Leave all the settings as the defaults and enter your email address.
- c) Click to refresh until the results appear. Two trees are displayed (a maximum likelihood solution and a Bayesian solution) but they are likely to be the same topology.
- d) Click *Download delimitation results*. The page that opens shows a list of groups (species) and the DNA barcodes contained within them.

Illustrative Example(s) or Case Studies

We have used DNA barcoding in several biodiversity studies in Southeast Asia (Wilson *et al.*, 2016) covering a wide range of animal groups including butterflies (Jisming-See *et al.*, 2016), bats (Syaripuddin *et al.*, 2014), sandflies (Polseela *et al.*, 2016; Sukantamala *et al.*, 2017) and dragonflies (Casas *et al.*, 2017). Two illustrative examples are provided below.

Butterflies of Setiu Wetlands, Malaysia

As part of the Setiu Wetlands Scientific Expedition organized by WWF-Malaysia in 2016, we conducted a survey of butterflies at Lata Changkah, Terengganu, Malaysia. All sampled butterflies were brought back to the laboratory and subjected to standard molecular methods for DNA barcoding (Wilson, 2012; Jisming-See *et al.*, 2016) and bioinformatics methods described above (see Sections Editing Sanger Sequences and Sequence Alignment). The DNA barcodes were submitted to BOLD where they are publicly available under the project code: SETIU. Species assignments were obtained on basis of >98% sequence similarity with records in BOLD (see Section BOLD identification engine), which was possible due to the existing DNA barcode reference library for the butterflies of Peninsular Malaysia (Wilson *et al.*, 2013). However, a strict tree-based criterion (Wilson *et al.*, 2011) was used to assign three DNA barcodes that did not share >98% similarity with any BOLD records to genera. Forty-nine species were recorded suggesting Lata Changkah can currently support rare butterflies (Sing and Wilson, 2017).

Sandflies of Northern Thailand

We collected sandflies using CDC light traps from five tourist caves in Northern Thailand. Specimens were brought back to the laboratory and subjected to standard molecular methods for DNA barcoding (Wilson, 2012; Jisming-See *et al.*, 2016) and bioinformatics methods described above (see Sections Editing Sanger Sequences and Sequence Alignment). We combined our new DNA barcodes with selected publicly available DNA barcodes in BOLD, which included species reported from Thailand (includes records from Thailand, India, and Sri Lanka). The combined dataset (394 DNA barcodes) is publicly available in BOLD under the code: DS-SFNTH. Using a combination of methods (see Sections BOLD Barcode Index Number (BIN) system and Neighbor-Joining (NJ) in MEGA), the specimens were clustered into 34 OTU. Several of the taxa thought to be present in multiple caves, based on morphospecies sorting, split into cave-specific OTU which likely represented cryptic species. The resulting species checklist and DNA barcode library contributed to a growing set of records for sandflies which is useful for monitoring and vector control (Polseela *et al.*, 2016; Sukantamala *et al.*, 2017).

Discussion

DNA barcoding is being used by researchers across an increasing number of biological fields reflecting the fact that DNA sequence information can be cheap and easy to obtain and can enable assignment of taxonomic names to organisms without requiring researchers to be familiar with intricate morphological features. Likewise, molecular OTU can be suitable surrogates for partitioning diversity into interoperable units for biodiversity studies enabling researchers to obtain taxonomic data much faster than possible with traditional morphological approaches, making studies scalable across much larger taxonomic groups and wider geographical regions (Wilson *et al.*, 2017). Yet, the prospect of DNA barcoding can be daunting for beginners (Wilson *et al.*, 2016). Mastering a basic bioinformatics workflow is essential to ensure the quality and reliability of data and to generate meaningful results (Wilson and Sing, 2013).

Future Directions

High-throughput sequencers are replacing Sanger sequencers in most molecular applications. The development of the sub-discipline of DNA metabarcoding grew directly from the major advantages offered by high-throughput sequencing through circumventing the sorting and isolation of the thousands of individuals in bulk mixed samples of organisms (Brandon-Mong *et al.*, 2015). However, the short read lengths and high error rates limited the use of high-throughput sequencers for conventional, individual specimen, DNA barcoding (Hebert *et al.*, 2017), and in particular, for DNA barcode reference library construction (Liu *et al.*, 2017). The continued reliance on Sanger sequencing has constrained reductions in the cost of DNA barcoding and led to uneven DNA barcoding efforts around the world (Liu *et al.*, 2017). Recently developed approaches using the latest generation of high-throughput sequencing platforms (Pacific Biosciences SEQUEL and Illumina HiSeq 4000) have produced full length DNA barcodes of equivalent length and quality to those generated by Sanger sequencing, but with substantially reduced costs of 10-fold (Liu *et al.*, 2017) to 40-fold (Hebert *et al.*, 2017). Bioinformatics pipelines to complement these new approaches have developed concurrently. The mBRAVE webserver developed by the team behind BOLD, and with direct links to the BOLD reference libraries (Hebert *et al.*, 2017) is an important development and likely represents a landmark shift in standard DNA barcoding protocols.

Closing Remarks

In this article, we provide beginners with step-by-step instructions for converting raw DNA sequences into clean DNA barcodes (sequence editing, sequence alignment), to commonly used tools for assigning taxonomic names to DNA barcodes, and to cluster DNA barcodes into OTU. As more researchers become comfortable with such bioinformatics workflows, and the DNA barcoding community continues to grow, essential questions for society: “What is this specimen on an agricultural shipment?”, “Who eats whom in this whole food web?”, and even “How many species are there?” become answerable (Adamowicz, 2015). It is promising

that capacity for DNA barcoding is growing in the parts of the world where it is needed most, particularly among the younger generation of researchers who can easily connect with the barcoding analogy (Adamowicz, 2015; Wilson *et al.*, 2016).

Acknowledgements

Kong-Wah Sing is supported by the Chinese Academy of Sciences President's International Fellowship Initiative. We thank the BOLD team, especially Megan Milton, for their continuous support of our DNA barcoding workshops in Southeast Asia. We are grateful to CodonCode Corporation for supplying teaching licenses during our workshops. We thank previous sponsors and hosts of our DNA barcoding workshops: the Centre of Excellence in Fungal Research, the Department of Microbiology and Parasitology, and the Faculty of Medical Science at Naresuan University, Phitsanulok, Thailand; the Zoological and Ecological Research Network, and Museum of Zoology at the University of Malaya, Kuala Lumpur, Malaysia; the University of Nottingham Malaysia Campus, Selangor, Malaysia; Tunku Abdul Rahman University College, Kuala Lumpur, Malaysia; and the Asia-Pacific Network for Global Change Research. Glossary

Co-reference References in a text that allude to the same thing using different names. Examples of co-references can be pronouns or abbreviations.

Corpus Collection of documents.

Manual curation Review and evaluation of data or information by humans.

Natural language Language that has evolved organically and thus has not been formally designed. Most spoken human languages are natural languages.

Pharmacovigilance Tracking of potential adverse events associated to marketed drugs.

Introduction

Biomedical text mining (henceforth, text mining) is primarily an applied scientific discipline. An important focus of text mining research is to increase the efficiency and efficacy of everyday biomedical work requiring the analysis of textual information. Due to the pervasiveness of text in the biomedical realm, text mining has applications in numerous settings, such as medical facilities, pharmaceutical and academic research institutions, etc. In each of these settings, however, there is interest in different questions, which can only be answered through the information contained in particular types of textual sources. However, each type of question and textual source brings its own challenges that necessarily condition the text mining tools that are used to answer them. Thus, text mining applications can be broadly organized around both the types of questions and the sources of text that are utilized.

Sources of Text

There is considerable variation in the writing style used within different textual sources. Notable differences can be seen between text mining applications for clinical settings, which deal with medical records, and those geared toward scientific text from scientific articles or grants. Similarly, text mining applications for social media or patents occupy their own niches. The reason for this is that each of these textual sources follows grammatical and semantic rules that differentiate them. These differences cause performance degradation in text mining tools that are applied to types of text that are different from the ones they were originally designed for. For example, patents may contain complicated claim dependencies (i.e., patent claims that make reference to other claims within the patent) that do not fit the natural language patterns that appear in other types of text. Another example of unusual writing style comes from social media, which is often ungrammatical and built with its particular contextual cues. It is worthy, thus, to discuss some of the different sources of text used in text mining before delving into particular applications.

Before discussing types of textual sources it is important to briefly point out the role that availability plays. Cost and privacy issues can be significant hurdles to access valuable biomedical information, thereby affecting the development of text mining applications. Free, electronic and easily downloadable content can more easily enable the development of such applications. With that in mind some relevant types of text sources are:

- Scientific abstracts: the main freely available sources are Medline and Europe PubMed Central (Europe PMC).
- Scientific full text articles: a growing subset of Open Access full text articles is available from PMC and Europe PMC.
- Patents: US patents are provided in bulk for free by the United States Patent and Trademark Office (USPTO). Other patent authorities typically require a fee for bulk electronic access.
- Grants: the main sources are the National Institutes of Health (NIH) RePORTER in the United States and the European Bioinformatics Institute (EBI) Grist database in Europe.
- Clinical trial records: ClinicalTrials.gov, the World Health Organization (WHO), and International Clinical Trials Registry Platform (ICTRP) are extensive free repositories that can be downloaded in bulk.
- Medical records and clinical notes: due to privacy concerns only limited samples are freely available, such as the i2b2 corpus.
- Pharmacovigilance and safety: pharmacovigilance records are available from the US Food and Drug Administration (FDA) FAERS and European Molecular Biology Laboratory (EMBL) SIDER databases. US drug labels are available from FDA's DailyMed.
- Social media: multiple blogs, microblogs, and forums can be downloaded from their internet locations. However, most of these sources require customized downloading and processing.
- News: freely available RSS feeds from news services, news agencies and newspapers provide an easy way to access current news content. Access to archival news is more limited (Breiner and Rodriguez-Esteban, 2012).

Documents coming from each of these sources are split into different sections, each with its own properties. For example, the abstract of a scientific article has a different structure, style, and content than the full text (Martin *et al.*, 2004; Schuemie *et al.*, 2004; Cohen *et al.*, 2010). Moreover, within document sections one can find structures, such as tables and figures, which require specialized processing.

Building Blocks

Text mining applications are often driven by the capabilities of the algorithms that have been the focus of most research attention in text mining. Such algorithms have both enabled and limited the applications that are currently possible. Thus, we may call these algorithms the “building blocks” of text mining applications. Where adequate algorithms do not exist, or yield low performance, applications become unfeasible. Examples of applications that have had very limited success for lack of effective algorithms are synonym detection (Cohen *et al.*, 2005), co-reference resolution (Kim *et al.*, 2012), and question answering (QA) (Yang *et al.*, 2014). Thus, any discussion on text mining applications needs to make a reference to the possibilities that are enabled by the algorithms that have been successfully developed thus far.

Some of these building blocks are:

1. **Named-entity recognition (NER).** One of the most studied areas in text mining is NER. NER consists in identifying specific types of names and other entities written in text. NER in biomedicine is faced with a particular set of challenges because some types of names that are of interest in biomedicine have large, complex vocabularies and can be uncommon in other realms. Examples of these are the names of diseases, genes, chemicals, drugs, mutations, cell types, and species. The precise identification of such names enables the extraction of other, more complicated facts. Therefore, high-quality NER is a prerequisite for many other text mining algorithms. Identifying such names by solely using lists of synonyms (a.k.a. concept recognition) does not often deliver results of acceptable quality (see Section “Evaluation Metrics”). Thus, there has been significant amount of work in machine learning algorithms to improve NER.
2. **Relation extraction.** A step further from NER is finding relations between pairs of entities. Many descriptions of biological and chemical phenomena involve multiple entities, such as the descriptions of signaling pathways, biomarkers, mutation–disease links, and drug–drug interactions. Descriptions of such phenomena may be simplified into a set of relations between pairs of entities. For example, a signaling cascade may be described by a set of individual protein-binding interactions. While such type of representation might be too simple for some applications it can still be useful to highlight relevant facts that can then be further explored.
3. **Event extraction.** In order to tackle more complex biological phenomena that may not be described adequately with relations, text miners have come up with the task of “event” extraction. Within this task an event is considered rather generically as a molecular status or change of status described in text (Kim *et al.*, 2008). An example of molecular event could be a translocation or a change in gene expression. Events can be multifaceted and conditioned by temporal and contextual parameters, which complicate their identification and the extraction of their details. Thus, more complex extraction and representation approaches are necessary to capture them and their different types of dependencies. Not surprisingly, the more complex the events that need to be extracted the more challenging it is for text mining algorithms. Thus, NER and relation extraction algorithms have achieved higher performance than those algorithms specialized in event extraction.
4. **Document classification and clustering.** Assigning a document to a specific class (classification) or grouping documents according to their similarity (clustering) is useful for certain text mining applications, such as for organizing and exploring the scientific landscape around a certain topic. It is also particularly useful for the task of selecting documents that can then be further analyzed or mined. Thus, an initial classification or clustering can reduce the work or improve the quality involved in later processing steps. This can be considered a “filtering” of documents. For example, due to the cost associated to accessing the full text of scientific articles, documents can be filtered first by the content of their freely available abstracts before accessing them.
5. **Document segmentation and zone detection.** As mentioned, many documents are divided into certain standard sections. For example, scientific articles are often organized into introduction, methods, results and discussion (IMRaD). Concentrating the focus of an application on particular sections can improve the quality of the results. However, the content of a document may not be appropriately located in the correct sections (Agarwal and Yu, 2009). Thus, recognizing the different segments and discursive zones of a document can help in its analysis. For example, by identifying the zones of a patent that deal with experimental setups one may get a better idea of the results that are being reported in the patent (Rodriguez-Esteban and Bundschuh, 2016).
6. **Co-reference resolution.** Generally, co-references (see Glossary) are challenging to mine, especially those that refer to something mentioned in another sentence in the text. On the other hand, a special case of co-reference that is easy to resolve is the abbreviation. Algorithms to map abbreviations to their definitions have been highly successful (Wren and Garner, 2002; Pustejovsky *et al.*, 2001), because abbreviations are often defined in the text in typical ways, where the abbreviation is followed by the definition in parentheses, for example, natural language processing (NLP).

Evaluation Metrics

It is important to consider the metrics used to rate the performance of text mining applications in order to be able to assess the quality of the results they provide. These metrics are similar to those used in information retrieval (IR). Two of the metrics are the counts of type I errors, known as false positives (FPs), and type II errors, known as false negatives (FNs). FPs represent items that

are incorrectly included in the results, while FNs are items that are incorrectly missing from the results. Moreover, true positives (TPs) are items that appear correctly in the results and true negatives (TNs) items that, correctly, do not appear in the results. Because in IR the number of TNs is often hard to quantify, or even conceptualize, performance metrics are based on TPs, FPs, and FNs. Two typical metrics that derive from them are precision and recall:

$$\text{precision} = \frac{TP}{TP + FP}, \text{ recall} = \frac{TP}{TP + FN}$$

Even though, precision and recall are widely used, finding a single metric has been always of interest because it makes comparisons easier across text mining applications. Thus, there are single metrics that have been devised to encapsulate the value of precision and recall, the most typical of them being the F-measure. The F-measure is the harmonic mean of precision and recall:

$$F = \frac{2 * \text{precision} * \text{recall}}{\text{precision} + \text{recall}}$$

Even though, it is the most widely used single metric, the F-measure has flaws and several alternative measures have been proposed, such as area under the curve (AUC) and overhead (Rodríguez-Esteban, 2009, 2015).

Another aspect to consider is that the use of multiple text mining applications to solve a problem can lead to an overall reduced performance as errors are compounded. As can be seen in Fig. 1, setting several text mining applications in series produces a degradation of performance as FNs and FPs accumulate at every step. Thus, increases in complexity of a text mining application may lead to results of lower quality, which in the end hinders our ability to identify complex phenomena in text.

Applications

Biomedical questions that can be answered using textual information are the engines behind the development of text mining applications. Such questions are context dependent because they change according to the settings and the textual sources available. Some of the questions that can be addressed with text mining are:

1. Questions that can be answered with relations. Questions that can be answered by mining relations are common in multiple biomedical contexts. Therefore, extracting relations is a major focus of text mining, especially for molecular-level relationships. In particular, the relations that have drawn the most attention have been the so-called protein–protein interactions (PPIs), which involve any relations between pairs of proteins or genes, whether direct or indirect (thus, not just protein binding). PPIs are useful to build signaling pathways and describe other phenomena, such as gene–gene co-expression. Another application based on extracting relations is the identification of biomarkers. There are several types of biomarkers (e.g., mechanistic vs. descriptive biomarkers, efficacy biomarkers, safety biomarkers). They typically involve a surrogate measurement of a biological effect that cannot be measured directly or it is costly to do so. Such surrogate measurements can be extracted from relationships in text, for example, by identifying downstream proteins in a pathological pathway or by extracting protein–metabolite relations. In addition to extraction of PPIs, many other applications are based on identifying relations. Identifying drug–drug relations can be helpful in clinical settings to discern pernicious drug interactions. Gene–disease and mutation–disease relations can lead to the identification of pharmaceutical targets, especially in cases in which the relation is causal. A subset of causal gene–disease relations, for example, are called perturbations, which are gene modifications that have been shown experimentally to improve or worsen a disease phenotype (Rodríguez-Esteban *et al.*, 2009). In the realm of pharmacovigilance, signal detection, which involves the flagging of potential drug-adverse event relations, is of great importance (Harpaz *et al.*, 2014). Another area of interest relates to pharmacogenomics, which is concerned with gene–compound relations (Garten and Altman, 2009).
2. Biological processes beyond relations. A relation is often an overtly simplified representation of a biological phenomenon. Events, on the other hand, can encompass even fairly complex descriptions of biological processes. Example applications that are based on extracting such biological processes are gene regulation, gene transcription, gene-variant-disease relations, protein catabolism, and phosphorylation. Protein phosphorylation, for example, may involve the identification of a kinase,

Fig. 1 Decreasing performance of serial text mining applications. When the input text needs to be processed by more than one text mining application the performance degrades.

- a substrate and a phosphorylation site (Hu *et al.*, 2005). Gene regulation, on the other hand, may involve the identification of genes that are expressed in particular cell types or anatomic locations (Gerner *et al.*, 2010). Gene-variant-disease relations present the challenge of identifying the gene associated to a specific genetic variant such as a mutation (Lee *et al.*, 2016).
3. Biomedical QA (BioQA). QA entails the answering of a natural-language question by seeking an adequate fragment of text that can function as an answer or that provides a fact that answers the question. QA is typically composed of two parts: (1) understanding the question being posed and (2) finding the fragment of text that correctly answers the question. In the biomedical setting, QA (or BioQA) can be used toward addressing questions that appear in real time, for example, questions from medical practitioners in clinical settings. Despite its potential usefulness, BioQA applications have not yet shown a level of performance that enables their practical use in such settings.
 4. Semi-automated curation. Many biological databases use text mining to filter documents or text snippets before they are evaluated by human curators and added to the database (Rodríguez-Esteban, 2015). This can significantly reduce the amount of curation effort that is spent while minimizing the number of relevant information that is missed through this filtering. The goal is to apply filters that have high recall and moderate precision. High recall ensures that there is a small number of FNs, while moderate precision leads to a reduction in the amount of items that need to be curated by avoiding potential FPs. Besides biological databases, text mining for semi-automated curation can be used for other tasks, such as for writing systematic reviews (O'Mara-Eves *et al.*, 2015). Graphical applications that enable semi-automated curation have been developed for many different curatorial settings (Rinaldi *et al.*, 2014).
 5. Biological similarity. All the text written about a biological entity can be used as a fingerprint of said entity. Because such text covers the knowledge that we have about the entity it can be used to make a number of predictions and comparisons. For example, all the documents mentioning a protein can be used together to predict the protein's function (Verspoor, 2014), its subcellular localization (Shatkay *et al.*, 2007), or its structure (Koussounadis *et al.*, 2009). Another example is similarity across diseases, which can be computed by analyzing the documents that mention each disease.
 6. Knowledge discovery. One can connect facts that have been extracted from different documents through the use of text mining. Because scientists are unable to follow all publications even in their own field they are prone to miss facts that could be relevant to their research. Thus, finding pairs or sets of related facts that are present in different publications ("connecting the dots") can lead to the discovery of knowledge that had not been evident to the individual scientists that contributed the facts. This way, for example, one may be able to explain the mechanism leading to certain adverse drug effects (Hristovski *et al.*, 2016) or anticipate future discoveries (Frijters *et al.*, 2010).
 7. Pharmacovigilance. Identifying reports of potential adverse events associated to specific drugs can be very time consuming, requiring the work of multiple human curators. Moreover, social media is becoming an increasingly relevant source of adverse event reports. Thus, there is a need to filter all the documents potentially associated to drug-adverse events to focus solely on those that are more likely to be relevant. Such filtering needs to be done carefully to minimize the number of FNs.
 8. Figure mining. Figures are integrated within many textual sources, such as patents and scientific articles. Thus, analyzing the content of figures requires mixing textual and image analysis. Applications of figure mining include figure classification (Rodríguez-Esteban and Iossifov, 2009) and linking an article's figures to text fragments within the article that explain the figure (Yu *et al.*, 2009).
 9. Landscaping and tracking biomedical knowledge. Following and landscaping biomedical trends can be useful to identify emerging technologies, areas of high research impact (Cokol and Rodríguez-Esteban, 2008; Cokol *et al.*, 2007), scientific trends (Rodríguez-Esteban and Loging, 2013) and novel discoveries, such as new pharmaceutical targets. Landscaping is of particular interest in patent mining, where it can be used to detect technological areas with low level of patenting (white spots) or to craft research strategies.
 10. Pharmacokinetics and systems biology modeling. Measurements and parameters that can be used for systems biology or pharmacokinetics modeling are difficult to identify using traditional search engines. Such numerical information can be better identified, for example, through rule-based approaches. Even more challenging is to associate these values to the relevant entity they describe. For example, to associate a protein concentration measurement to the protein that was measured.
 11. Enrichment of genomic analyses. Typically, genomic data, coming from high-throughput experiments, such as genome-wide association study (GWAS), pharmacogenomics, microarray, and RNAseq, can produce long lists of genes that need to be prioritized or grouped to further analyze their function or to decide on follow-up experiments. Text mining can help manage such lists in a high-throughput manner by parsing the literature associated to each gene (Ailem *et al.*, 2016) and providing an overall picture, for example, of the pathways and functions most often associated to a group of genes of interest. Such text mining results can be complemented with data from biological databases to create an integrated approach.

Conclusions

There are multiple ways in which text mining applications can impact biomedical work. A few have been discussed here but more can be explored within the text mining literature. See the Further Reading section for additional information on this topic.
